Multiple Sclerosis of Commotional Origin.—Ducamp and Milhaud refer to our new knowledge that shell concussion can without any sensible trauma cause multiple sclerosis, and report a case in detail. The subject was not treated until a year after his accident which occurred in February, 1916, and after sojourn in different sanitary formations was mustered out as a chronic invalid. The period of incubation was about a year and the initial symptoms pains in the loins and right leg. No special area of nerve distribution was involved. The sensations at first came on only when fatigued. He continued in active service for some months before he was interned in the hospital, and his symptoms apparently called for lumbar puncture, which act was productive of benefit but no light was thrown on the diagnosis. After a series of therapeutic punctures he developed paralysis in the right arm and leg, with sphincteric troubles. There were also disturbances of vision. After some weeks the paralytic symptoms receded and for the time the condition was negative. Careful neurological examinations showed anomalies of gait and a slowing of voluntary movements. There was an intention tremor when a glass was carried to the mouth. The patellar reflexes were exaggerated. Babinski on the right side was positive, excluding hysterical paralysis. Eyes normal save for slight nystagmus. Tongue protrudes normally. In general, neuroses could readily be excluded. The diagnosis was made apparently through an observation by Bernheim published many years ago of multiple sclerosis following a bombardment, together with the resemblance of the symptoms to the early stages of this affection. It is believed that the concussion causes small hemorrhages which form foci of disease after the elapse of about a year.

Role of the Ovary.—Labhardt attempts to differentiate between hypo-, hyper- and dysfunction of the ovary in the clinic. In hypofunction we must have absolute or relative amenorrhea although we may find that in some of these cases ovulation and formation of corpora lutea persist indefinitely. Again after an interval of silence ovulation may begin anew. The clinical picture may at times be confused by other phenomena but nevertheless hypofunction means amenorrhea. When adiposity is added it means that the metabolic function of the ovary is also depressed. Further some sterility is also due to ovarian hypofunction which involves suppression of ovulation. Either the ova do not mature or the follicles do not rupture. Still another manifestation seen in the undeveloped is genital infantilism with or without confusion of secondary sex characters. Again chlorosis should be included under the effects of ovarian hypofunction. There are also numerous double and pluriglandular syndromes in which ovarian activity is depressed. The part played by subfunction of the ovary in various constitutional states is evident but not decisive as enteroptosis and other constitutional inferiorities. In regard to dysfunction the most striking clinical expression is certain menorrhagias but not those characterized by long duration or excessive flow. Disturbed cycle is the evidence of ovarian dysfunction and this alone. In other words increased frequency or the precocious supervention of the flow shows that ovulation is precocious. Naturally in dysfunction hypofunction may coexist. Further in dysfunction we may see various anomalies of the genitals and organism at large and the author mentions vaginitis and uterine discharges, pruritus of the vulva, and, of general states, vagotonia. Of pure hyperfunction we know but little—it is responsible for precocious puberty and osteomalacia.

Book Reviews.

PHYSIOLOGICAL PRINCIPLES IN TREATMENT. By W. LANGDON BROWN, M.A., M.D., Cantab., F.R.C.P. Physician, with Charge of Out-Patients, St. Bartholomew's Hospital; Physician to the Metropolitan Hospital, etc. Fourth edition. New York: William Wood & Co., 1920.

THE many advances made in medical science during the five years that have elapsed since the appearance of the third edition of this interesting little volume have called for a thorough revision of the text and the entire rewriting of the chapters on Diabetes and Acid Intoxications. The chapters, as now arranged, embrace the principles of organotherapy; the rational treatment of gastric disorders; mechanical factors in digestion and indigestion; the work of the pancreas; uric acid and the purin bodies; oxaluria, phosphaturia, and urinary calculi; albuminuria and the treatment of nephritis; glycosuria and diabetes; acidosis and acid intoxications; intestinal intoxications; irregular action of the heart; the vasomotor system in disease; cyanosis, vitamines and calcium salts. The bibliography, arranged according to chapters and subjects, is placed at the end of the text. A comprehensive index and a list of authors complete this volume of 427 pages.

PENSIONS AND THE PRINCIPLES OF THEIR EVALUATION. By LLEWELLYN J. LLEWELLYN, M.B. (Lond.) and A. BASSETT JONES, M.B. (Lond.) Temp. Captain R.A.M.C. With a section on Pensions in Relation to the Eye by W. M. BEAUMONT, Acting Ophthalmic Surgeon to the Bath War Hospital. Price, $8.50. St. Louis: C. V. Mosby Company, 1919.

THIS volume is the American imprint of a British book issued during 1919 and contains an introduction for American readers by Dr. Sever of Boston. The number of pages is 702 and the 29 chapters cover history of the pension system. Legislation, temporary pensions, special clauses in pensions, examination for pension claims, origin of the disability, evolution and gravity of the same, adaptation to disabilities, principles of evaluation, ankyloses, fractures, scars, injuries to nerves, lesions of muscles, tendons, joints and bones, amputation, injuries to the eye and vision, injuries to the ear and deafness. The authors acknowledge their obligations to the American authorities, Burton J. Hendrick and Charles Francis Adams.

A DIABETIC MANUAL for the Mutual Use of Doctor and Patient. By ELLIOTT P. JOSLIN, M.D., Assistant Professor of Medicine, Harvard Medical School. Second Edition. Philadelphia and New York: Lea & Febiger, 1919.

IN diabetes more than in any other disease, successful treatment is dependent upon the trained and intelligent cooperation of the patient. In fact the patient practically treats himself and the physician need exercise only occasional supervision. Such a manual as this of Joslin's is therefore a necessity for the use and training of the patient. But it will prove of immense aid also to the physician. It is written with satisfying detail and in language that the layman can understand. In this second edition the advances of the last few years have been incorporated and it is up to date in every respect. The illustrations are well chosen and presented. The tables are invaluable. The reports of the analyses of the so-called diabetic preparations are of tremendous help in teaching the diabetic the need of care in choosing his food and the unwisdom of relying blindly upon advertisement. The recipes will be helpful to the patient's cook. The book is a valuable one and we predict for it a long popularity.

SYMPTOMS IN THE DIAGNOSIS OF DISEASE. By HOBART AMORY HARE, M.D., B.Sc., Professor of Therapeutics and Diagnosis in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital. Eighth Edition. Philadelphia and New York: Lea & Febiger, 1920.

THE opening sentence of the preface to this eighth edition of Dr. Hare's book is one about which useful sermons could be preached and it is an admirable basis upon which to build such a work as this. He says, "Laboratory investigation, by the brilliancy of its results in obscure cases, has served to divert attention from the careful study of the patient which is usually the chief method by which a correct diagnosis can be made." If this work did nothing more than to impress upon the mind of the reader the importance of this fundamental truth it would perform a greater service to medicine than many other far more pretentious volumes. The most dangerous weakness of the medical student of to-day is his supine reliance upon the laboratory for diagnoses. This is due in large part to his inability to elicit and interpret symptoms and physical signs. It is by the study of such books as this that the above tendency may be overcome and it is gratifying to see that the demand for the book has been so great as to call for an eighth edition. Many of the profession are already familiar with the plan of the work. It discusses symptoms and their significance and is written upon the plan of the upbuilding of a diagnosis by grouping the symptoms. The new edition has been thoroughly revised and is profusely illustrated with well-chosen photographs and drawings. It will be found to be very complete and will no doubt have the same popularity as the former editions.

HERMAN'S DIFFICULT LABOUR. A Guide for Students and Practitioners. Sixth Edition, Revised and Enlarged, by CARLTON OLDFIELD, M.D. Lond., F. R. C. S. Eng., Hon. Obstetric Surgeon to the General Infirmary, Leeds; Lecturer on Gynæcology, University of Leeds; Late Hon. Surgeon to the Women and Children's Hospital, Leeds; Hon. Medical Officer to the Maternity Hospital, Leeds. With 198 illustrations. New York: William Wood and Company, 1920.

TO many of the older practitioners Herman's "Difficult Labour" is well known as a trusty guide and friend. The author has a wonderful faculty of telling in clear language what is the best way of dealing with each of the possible complications of labor. One of the many charms of the book is the way in which the author avoids confusing his reader with the mention of all the different views and theories which have been held. In place of this, the common way, he selects the one or two methods which his experience has shown to be of most value. The editor has performed a real service in bringing this classic up to date, and it is to be hoped that another generation will enjoy a book which was a prime favorite with their predecessors. The fine quality of the printing and illustrations add to the attractiveness of the volume.

CUNNINGHAM'S MANUAL OF PRACTICAL ANATOMY. Revised and Edited by ARTHUR ROBINSON, Professor of Anatomy in the University of Edinburgh. Seventh Edition. Volume Second. Thorax and Abdomen. With 231 illustrations, many of which are colored. New York: William Wood and Company; Edinburgh, Glasgow, and London: Henry Frowde and Hodder and Stoughton, 1920.

THE first volume of the new edition of this standard work was noticed in the MEDICAL RECORD of July 31; the present volume contains the discussion of the thorax and abdomen. We have noticed a number of new illustrations, and the description of the dissections has been largely rewritten. This work early maintains its position in the lead of books of its kind; and, with the possible exception of the bones, it contains almost all the anatomy which the practitioner uses in his daily work.

THE PROBLEM OF THE NERVOUS CHILD. By ELIDA EVANS. Introduction by C. G. JUNG, M.D., LLD. New York: Dodd, Mead & Co., 1920.

HERE is a book the physician can advantageously place in the hands of parents. Addressed to those who have the care of nervous children it can nevertheless be used with great benefit by any parent. The usual mistakes in handling children are pointed out, those both of too great leniency and of undue severity. It is from these that there develop later the neurotic patients, those hysterics and neurasthenics who are the bane of the general practitioner. Such books as this are the prophylactic measures which, if duly used, will make the next generation far healthier mentally. Mrs. Evans has not only pointed out the pitfalls, but she has indicated the roads to follow. On the whole, the book is a notable addition to the increasing literature of mental hygiene and the physician who becomes acquainted with it will naturally seek to pass it on to the parents among his patients.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-fifth Annual Meeting, Held in Atlantic City, May 4 and 5, 1920.

DR. HERMANN M. BIGGS, PRESIDENT, IN THE CHAIR.

First Day—Tuesday, May 4.

(*Concluded from page* 251)

Epinephrin Hypersensitiveness and Its Relation to Hyperthyroidism.—Drs. FRANCIS W. PEABODY, CYRUS C. STURGIS, EDNA H. TOMPKINS, and JOSEPH T. WEARN of Boston presented this paper, read by Dr. Peabody. They stated that epinephrin hypersensitiveness, as indicated by the "positive" reaction after injections of epinephrin according to the method of Goetsch, had become so generally regarded as of specific diagostic significance in hyperthyroidism that it had seemed to be of importance to study in more detail the conditions under which it might occur. A study of the reaction in normal individuals showed that it was not present in any of the group of 26 seasoned soldiers; it was present in 14 per cent. of 28 medical students and in 48 per cent of 103 soldiers without evidence of organic disease but with the symptom complex of "effort syndrome." Seven psychoneurotics all gave "positive" reactions. Among hospital patients it was found that 17 per cent. of 17 patients with organic heart disease and 57 per cent. of 21 patients convalescent from acute infection gave "positive" reactions. "Positive" reactions to epinephrin were found in 15 out of 21 cases of hyperthyroidism. Six unquestionable cases with metabolism within 21 and 35 per cent. above normal gave "negative" reactions. On account of the wide distribution of the reaction among persons in whom there was no evidence of hyperthyroidism it should certainly not be regarded as having any specific significance in the diagnosis of this condition.

Dr. M. H. FUSSELL of Philadelphia said that he was very pleased to hear these observations on the soldier with effort syndrome. The so-called Goetsch test had been widely accepted as a positive indication of hyperthyroidism. The unreliability of such a conclusion was now shown. Dr. Fussell said he had a patient who gave a very active reaction to the Goetsch test, but the basal metabolism was not above normal. He had nervousness and tachycardia and he asked to be operated upon on the ground of a positive Goetsch test.

Dr. ROUNTREE asked if these hyperthyroid cases were of the Graves' type, or were they toxic adenomata. Was there any difference between the toxic type and the exophthalmic type?

Dr. C. C. STURGIS of Boston, replying to Dr. Rountree, said that only two were cases of adenomata. He was glad to hear that the clinical experience of others agreed with theirs. He had begun to feel that placing reliance on the test was pretty dangerous.

The Hepatic Margin of Safety in Bile Elimination.—Drs. PEYTON ROUS and PHILIP D. MCMASTER of New York presented this topic. They had studied the question as to how much obstruction of the biliary system was required for the production of a clinical jaundice. No studies had been recorded on this point. The authors found that the bile ducts from more than 80 per cent. of the dog's liver could be obstructed without the appearance of bile constituents in blood or urine, and from more than 95 per cent. without the appearance of tissue icterus, such as regularly ensued when obstruction was total. In monkeys the margin of safety was approximately as great. There was an additional element of safety in the hypertrophy of the liver portion with duct left free, which occurred rapidly under the conditions of local obstruction. It followed from these observations that clinical jaundice could scarcely be the result of local obstruction. When it occurred in connection with a circumscribed liver lesion one must suppose that the liver as a whole had been influenced by this latter.

Dr. S. J. MELTZER of New York said that Dr. Rous had spoken of factors of safety. If 95 per cent. of the liver was obstructed, then the five per cent. left must be a margin of safety. Did Dr. Rous remove three-fourths of the liver? Tying off was not the same as removing. Often something happened in the liver to disturb the ligation and circulation was re-established.

Dr. G. H. WHIPPLE asked if Dr. Rous had observed any cutting through of the ligatures. That had often been found a troublesome point. The ligatures would sometimes cut through, and he thought this might happen in a small duct as well as in the common duct. A remarkable concentration of the bile occurred in the fasting animal.

Dr. ROUS said that the term factors of safety had become a cant phrase. In the experiments three-fourths of the liver were removed. The liver manufactured the bile pigment, and it was necessary to know what became of the bile substance. So far no satisfactory tests had been devised for bile pigments. In their work they had cut through the duct wherever possible and had obliterated the duct above. The bile became very concentrated with fasting. The jaundice in connection with fasting occurred very rapidly, but bile stasis took three or four days to be produced.

Cultures of Diphtheria Bacilli in Whole Coagulable Blood.—Drs. SOLOMON SOLIS-COHEN and GEORGE D. HEIST presented this communication. In previous papers they had treated of the bactericidal or inhibiting power of whole blood for pneumococci and other bacteria. In the present study the diphtheria bacillus was examined by the same methods. Diphtheria bacilli were cultivated in capillary tubes of defibrinated blood. They grew rapidly and vigorously. The rather scanty air supply did not hinder their growth. The guinea pig was very susceptible to infection by the diphtheria bacillus, while the rat was almost immune. Diphtheria bacilli were cultured in the whole blood of these two species. In guinea pig blood the bacilli grew almost but not quite as well as in defibrinated blood. The blood of the pig possessed a slight resistance to diphtheria bacilli. On the contrary, in rat blood diphtheria bacilli grew very poorly. In the case of these two species then, there was a correlation between the resistance of the blood to diphtheria bacilli in vitro and the actual resistance of the animal to infection. Diphtheria bacilli were grown in the whole blood of children and at the same time a Schick test was done on the child. The whole blood of children was highly bactericidal for bacilli which had been artificially cultivated for 20 years. The authors used the Park and Williams strain No. 8. A strain fresh from a case of diphtheria was found to grow much better in whole blood, but still there was a marked bactericidal action. They tested 160 children in this manner. There seemed to be little or no relationship between the resistance of the blood to diphtheria bacilli, and the resistance of the child to diphtheria as shown by the Schick test. The susceptibility of the guinea pig and of the child seemed to be of a different character. The prolonged cultivation of diphtheria bacilli lowered their ability to grow in whole human blood, but it did not appreciably lower their toxin-producing power.

Dr. E. C. ROSENOW of Rochester, Minn., asked whether the blood results agreed, and whether there was any coagulation of the blood in the tube which might have exerted influence that way.

Dr. COHEN said that the work was developed to test out as many organisms as possible, or to determine what relation there was between the blood and resistance to different organisms. Work on micrococci and pneumococci had given corresponding results. The importance of the work was to test immunity in human beings to bacterial invasion, and to see if there was any relation between this and the bactericidal effect of the blood as studied in the test tube. If this could be shown there would be a distinct advance. The criticism that the action was inhibitory and not bactericidal was possibly true, but there was found to be a distinct bactericidal value which could be expressed in terms of time; if no growth occurred within a certain time, a certain number of bacteria had been killed.

Dr. ROSENOW asked how the culture was inoculated, and how they got an even distribution.

Dr. HEIST said that it was inoculated on the surface of the solid agar. He took a loop-full with 5 c.c. of saline solution, shaking it up thoroughly, put it on the blood and spread it thoroughly with a glass rod. The blood was allowed to clot in a capillary glass tube

Clotting probably had an important bearing, as it gave the leucocytes some scaffolding, as it were, to work upon. In the diphtheria work phagocytosis was a very important factor, but there might be some other as well. Opsonins were probably present in the serum, but whole blood would be different from serum. Whole blood would be necessary, as citrated blood would interfere with the test.

The Blood Sugar Tolerance Test as an Aid in the Diagnosis of Gastrointestinal Cancer.—Drs. JULIUS FRIEDENWALD and GEORGE H. GROVE of Baltimore presented this paper. They referred especially to the work of Rohdenburg, Bernhard, and Krehbiel who had published two papers on the glucose tolerance in cancer The difficulties arising in the diagnosis of gastrointestinal cancer, especially in the early stages, led Friedenwald and Grove to make a further study of the blood sugar tolerance test as an aid in the differential diagnosis between carcinoma and other diseases of the abdominal organs. They followed the plan of administering after a night's fast 100 grams of dextrose dissolved in 300 c. c. of black coffee without additional sugar. The blood was withdrawn for examination just before the dextrose was given and again 45 minutes and two hours after its administration. The blood sugar tolerance was studied in thirty-two cases of carcinoma of the gastrointnestinal tract. Of these patients seventeen were operated on, and the diagnosis was thus confirmed, while the others were all typical of the disease. In addition blood sugar tolerance tests were made in uterine carcinoma, breast cancer, carcinoma of the prostrate, sarcoma, and many cases of nonmalignant disease of the gastrointestinal tract. The authors classified the sugar tolerance curves into the following groups: (1) The normal curve in which the blood sugar rose not usually above 0.16 per cent within forty-five minutes, falling gradually within two hours to about the level as observed in the fasting state; (2) The atypical normal curve as found in cases of achylia gastrica in which the blood sugar was practically normal in the fasting state, ascending to 0.16 to 0.19 per cent within 45 minutes after taking the dextrose, and falling within two hours to 0.13 to 0.15 per cent but not lower; (3) The intermediate curve found in cases of carcinoma not associated with the gastrointestinal tract in which the blood sugar was comparatively high, even in the fasting state 0.14 to 0.17 per cent, and in which after the ingestion of the dextrose there was a rise to from 0.20 to 0.23 per cent within 45 minutes, followed within two hours to a fall of from 0.18 to 0.21 per cent, but not descending to the level of the fasting state; (4) The cancer curve found in carcinoma of the gastrointestinal tract in which, even in the fasting state, there was a high sugar content of from 0.14 to 0.17 per cent, followed after the ingestion of the dextrose by a rise of from 0.21 to 0.24 per cent or higher, within 45 minutes, remaining at this level for at least two hours and at no time during this period falling below 0.20 per cent. From their study of the blood sugar tolerance test, in health as well as in the various affections of the gastrointestinal tract, the following conclusions were drawn: (1) There was present in carcinoma of the gastrointestinal tract usually a characteristic curve of sugar tolerance which in no way approximated the normal and differed somewhat from that observed in carcinoma of other regions of the body. The curve of this affection presented a high sugar content, even in the fasting state, followed by an initial rise up to 0.24 per cent or higher, within three-quarters of an hour after the ingestion of the dextrose, remaining at this level for at least two hours and at no time during this period falling below .20 per cent; (2) The sugar tolerance test was rather distinctive so that it might render valuable assistance in a large proportion of cases as a means of differential diagnosis between carcinoma and other diseases of the gastrointestinal tract; (3) The opportunity had not been afforded to test a sufficient number of early cases of cancer of the stomach and intestines, according to this method, so that as yet the value of this test as a means of early diagnosis had not been established, nevertheless, as positive curves occurred equally whether cachexia existed or not, or whether the extent of the involvement were slight or great, the authors were under the impression that the results might be quite definite, even in the early cases of the disease. This question, however, would require further study; (4) Finally, while Friedenwald and Grove fully realized that this test could not be relied upon alone without entering into the clinical aspects of the disease, and that there were cases of carcinoma in which negative findings might occur or non-malignant conditions in which the results might be positive, nevertheless they were of the opinion that when properly performed the blood sugar tolerance test might be of considerable diagnostic help in obscure cases of carcinoma of the gastrointestinal tract.

Studies of the Acid Base Equilibrium in Disease from the Point of View of Blood Gases.—Drs. J. H. MEANS and A. V. BOCK of Boston presented this topic. Dr. Bock stated that L. J. Henderson had shown that the acid base equilibrium of the blood was dependent chiefly upon the ratio of dissolved carbonic acid to bicarbonate. Haggard and Y. Henderson had put these relationships into graphic form in what they called the carbon-dioxide diagram of the blood. The diagram consisted essentially in a plot of the carbon dioxide dissociation curve of the blood with a mark upon the curve at the point at which the coordinate representing the arterial carbon dioxide tension intersected it. This point they called the arterial, or A point. A straight line called the OC line drawn through the zero and A points of a normal blood would represent the normal hydrogen ion concentration. The diagram thus demonstrated not only the presence of acid in the blood as shown by the level of the dissociation curve but also whether any change in hydrogen ion concentration had occurred as shown by the position of the A point. Such diagrams of the blood of five patients were shown. A diabetic with marked acidosis had a very low dissociation curve denoting a large amount of acid in his blood but a perfect compensation as shown by the position of the A point upon the CC line. A cardiorenal patient with intense retention acidosis had a still lower curve and an actual shift in the reaction of his blood, as shown by the position of the A point on the acid side of the CC line. The diagram obtained the next day with the blood of this same patient after he had been given great quantities of alkali showed a curve higher than normal and an A point on the alkaline side of the CC line. A case of lobar pneumonia showed an essentially normal diagram and a case of influenza pneumonia showed a normal dissociation curve but an A point displaced in the acid direction. A case of post-operative bronchopneumonia showed a curve higher than normal but an A point displaced in the acid direction. It was concluded that the carbon-dioxide diagram furnished a more comprehensive means of interpreting disturbances of acid base equilibrium than did a study of either plasma bicarbonate or alveolar carbon dioxide tension alone. In some cases of pnuemonia there might be carbonic acidosis due to insufficient pulmonary ventilation.

Dr. C. F. HOOVER of Cleveland asked if Dr. Bock found his results inconsistent with the anoxemia of pneumonia and of anesthesia which was due to the contribution of unexpired blood in the aortic stream. In these patients giving them pure oxygen would not move the cyanosis. There was an interstitial edema, just as in edema of the lungs with multiple thrombi. The cyanosis from alveolar edema could not be moved and the CO_2 was not modified at all; but in a man with phosgene poisoning giving oxygen would modify the cyanosis. The phosgene patient could not tell whether he was breathing oxygen or air.

Dr. BOCK said he could not explain the anoxemia. He thought what Dr. Hoover said was correct, and that CO_2 was apparently accumulating. They determined the oxygen to find out what oxygen was present. The accumulation of CO_2 would show that the ventilation was insufficient.

Dr. HOOVER said that recently Haldane had stated that anoxemia was due to the rapid breathing, but one also found anoxemia with slow breathing.

Dr. BOCK said the patients did not seem to expire the CO_2. They could not get rid of it.

Dr. HOOVER said they did in a measure compensate for the CO_2 but not for the anoxemia.

Dr. BOCK said these patients could not accomplish ventilation enough to preserve the ratio.

Effect on Blood Pressure and Blood Nitrogen of the Ingestion of Large Amounts of Fluid.—Dr. JOSEPH L. MILLER read this paper in which he said that large amounts of fluid were administered to patients of various type, to study the effect on the non-protein nitrogen. The water was introduced by the Rehfuss tube, 2½ liters every three hours, till hydremia was produced. The blood nitrogen was then determined. The urine output was measured and the patient weighed before and after each period of the water intake. All the patients tested were those with high blood pressure, and a steady rise was observed. In one man the blood pressure rose from 160 to 280, and the weight from 124 to 142 lbs. during the day. The next day the blood pressure fell, but he complained of dyspnea and distress. Water administered to the same patient at three-hour intervals during the night caused the blood pressure to rise from 170 to 260 and the weight to rise 9 lbs. The blood urea or 34 mg. urea nitrogen per 100 cc. blood, before the test, and slightly more after it. There was a 50 per cent reduction in uric acid, but the creatinin was unchanged. In the other patients (3) tested, the results were comparable. In one patient suffering from gout, who passed large amounts of water immediately after ingestion, the blood pressure was not affected. The conclusions of the author was that ingestion of large amounts of fluid had no effect on urea nitrogen, though there was reduction of the uric acid.

Intrathoracic Teratomata.—Dr. SAMUEL W. LAMBERT of New York made this presentation. Under teratomata he included dermoids. These growths ran a characteristic course. They were congenital, grew until puberty, and then became quiescent. They occasioned slight pressure symptoms. The shape was a characteristic spherical one, and they were usually located in the anterior mediastinum. In one case, the radiographs of which were shown, the patient, male, a hodcarrier, was supposed to have developmental error of the vertebræ. The true diagnosis was made by following the tumor, through a series of pictures, for a long time. It was possible that malignancy might be the end of such cases. Dr. Wood made the autopsy on this case and found a large adherent tumor with irregular tissue sections characteristic of teratomata. There was a great variety of tissue-cartilage, bone, solid epithelium, squamous, celled epithlium, and possibly beginning nasopharyngeal structures.

Dr. J. B. HERRICK said that his autopsy studies were made on the patient who was followed for over a year. Fluoroscopic examination indicated there was no aneurysm. It was thought there was a dilated right auricle. The tumor was more attached to the pericardium than to the auricle. It was semi solid, filled with cholesterin crystals. Such tumors within the pericardium were very rare.

Dr. HOBART A. HART asked if Dr. Lambert excluded gonococcus infection by the complement fixation test. The spherical cysts were usually quiescent.

Dr. C. CANBY ROBINSON of St. Louis said he noted there were eight ounces of pus. Was there anything to confirm the diagnosis of teratoma? Some aneurysms produced no physical signs. He had shown a considerable number of plates of wired aneurysm. There was a very irregular outline in some of the plates which helped in the diagnosis. This fluoroscopic irregularity differentiated tumor from aneurysm. He had collected statistics as to mediastinal growths and found that dermoid cysts were rare, according to the literature. One should pay more attention to the mediastinal contents. He had been surprised to find how many cases came to the dissecting room. Most extraordinary changes could be found with reference to the peribronchial lymph nodes. Many fevers might be due to secondary suppurative changes in tumor formation. These were overlooked very often and in any cases of unexplained fever one should think of the mediastinal lymph nods. Many workers paid no attention to these tissues.

Dr. LAMBERT, in closing, said that he had read of one case of dermoid cyst within the pericardium. Tests were not made by the complement fixation for gonococcus. He did not believe these cases were quiescent, as Dr. Hart said. In the case illustrated, no hair was discovered. The pus was examined very carefully. Fluoroscopic tests did not show any evidence of aneurysm. All the cases had a negative Wassermann. Some had been given provocative treatment with salvarsan in the endeavor to bring out this point.

Experiments on the Therapeutic Action of Radium and Roentgen Rays.—Dr. FRANCIS CARTER WOOD of New York presented this topic, illustrated by lantern slides. Experiments were made to determine the value of radium and the *x*-ray as adjuncts to surgical treatment. Quantitative methods had been applied in the past, but hardly two men were agreed as to dosage and method, thickness of screening, etc. Thus it was hard to determine how much dosage was necessary to produce a cure. Scar tissue rendered the tumor quiescent, but recurrence might take place in the lymph nodes after as long a period as ten or fifteen years. The scar tissue prevented the tumor cells from gaining nourishment. It was essential to ascertain the amount necessary to kill the cancer cell. In the transplantable tumors of animals experiments had been made to determine the lethal dose of radium under filtration, and also the lethal dose of the *x*-ray. It was attempted aso to discover the biological difference between soft and hard *x*-rays. The valuation of continuous and of intermittent dosage was tested, to determine whether the cell was killed by intermittent as well as by single doses. Also tests were made to see if there was anything in the quantity, whether a large quantity for a short time was as effective as a small quantity for a long time. Experiments were also made as to the effect of heat on the tissues, and it was found that heat could be used as effectively to kill the tumor cell, and at a point at which it would be impossible to carry the *x*-ray or radium, that is at which *x*-ray mortality would be higher than surgical mortality. If the action of heat to the tissues could be used to supplement *x*-ray and radium therapy one could see the possibility of the cure of cancer within reach.

Paroxysmal Tachycardia of Ventricular Origin and Its Association with Coronary Thrombosis.—Drs. G. CANBY ROBINSON and GEORGE R. HERRMANN of St. Louis presented this communication, which dealt with rapid heart rate associated with an abnormal point or origin of the cardiac impulse. The ectopic origin of the impulse might be in one of the auricles or ventricles, and the ventricular cases were rare and of more serious prognosis. Lewis in 1919 found that this condition occurred in dogs in which the coronary artery had been ligated. The nutrition of the ventricular wall became impaired. This was the result of interference with the coronary circulation. Electrocardiographic records were necessary for diagnosis. A ventricular rate of 150 or more was noted. In all undoubted cases in the literature the patients were middle aged men. In one, autopsy showed atheroma of the left coronary. Of four patients, three died. One man had antiluetic treatment.

The Heart in Influenza, with Electrocardiographic Studies.—Dr. WALTER W. HAMBURGER of Chicago read this paper. The question as to whether inflenza affected the heart was unsettled. McKenzie had minimized the effect, but Lewis was inclined to take the other point of view. Pathological reports from the army camps showed that, grossly, the heart muscle was not affected, but microscopical changes could be found, such as vacuolization and other degenerative findings. Among the English reports, Conklin showed that influenza picked out the conduction system and affected the auriculoventricular nodes. There were three types: (1) in the fatal group the myocardium was affected; (2) in acute, but not fatal, cases the heart muscle findings cleared up after several weeks; (3) the subacute or chronic cases did not clear up. There was no question but that influenza infection did affect the heart muscle and that it had a definite effect on the auriculoventricular system.

Nodal Rhythm, with Reverse Block and Paroxysmal Tachycardia.—Drs. M. H. FUSSELL and C. C. WOLFERTH of Philadelphia made this presentation. Dr. Fussell said that auriculoventricular rhythm had been noted by many workers and it could be experimentally produced by interference with the impulse of the auriculoventricular node. The majority of cases were due to depressive influences. In a case of functional paroxysmal tachycardia in a woman of 62, the attacks

had persisted since childhood, becoming more frequent as she grew older. For two years she had been invalided. She was able to control the attacks sometimes, but not always, by taking a deep breath and holding it.

The Causal Factors for Emphysema Attending Bronchiolar Hypertonus.—Dr. C. F. HOOVER of Cleveland read this paper. The speaker said that one saw the statement made that emphysema was due to expiratory dyspnea. The expiratory effort was not as strong as the inspiratory one. This fact had little support. Another theory was that the thorax first became enlarged and then the lung became deformed. The diaphragm was the most mobile boundary of the thoracic cavity. In bronchiolar spasm there was increase of the three dimensions of the lung. In testing by the Benedict test one assumed that the inspiratory and expiratory consumption of oxygen and the effort was 25 per cent. more. There was a difference between obstruction of the bronchus and that of the bronchiole. If there was obstruction of the bronchus there was diminution in the lung. Less air entered the obstructed lobe. The lower right costal margin tended toward the median line in inspiration. Adrenalin would cause it to move out again. Obstruction of the trachea was very rare without secondary bronchitis. In the case of a young girl of 17 years, there was the utmost effort to inspire. There was severe stenosis of the trachea, but no enlargement of the lungs. The patient literally died from strangulation. In a man who had a large aneurysm compressing the trachea there were attacks of dyspnea. As he inspired he lifted the aneurysm. The air escaped with the systole of the aneurysm. There was severe expiratory dyspnea, but no emphysema. In emphysema there must be collapse of the lung without expansion. With any expansion or increase in the size of the lung there was no emphysema. There was a great lack of knowledge of the motility of the lung.

Prognosis in Cardiovascular Disease with Special Reference to the Application of Graphic Methods.—Drs. JAMES D. HEARD and Dr. GEORGE E. HEIN of Pittsburgh presented this topic. The object of their investigation was to determine the clinical value of electrocardiograms in a routine collection in a general hospital. Studies of 780 patients were made. The limitations of the study were great on account of the impossibility of following patients up and because of the faulty histories. The source of the material was interesting; 61 per cent. came from the medical department, 60 per cent. were males, with an average age of 67 years; there was rarely definite evidence of syphilis; 14 per cent. died. Most of the patients were of the type described as cardiosclerotic cases. Possibly some were of the functional type, but not many, and low amplitude was evidenced as the patients grew worse. This showed a parallel with the clinical gravity of the cases. The prognosis had to be made with caution.

The Hereditary Factors in the Resistance of Tuberculosis.—Drs. PAUL A. LEWIS and SEWELL WRIGHT of Philadelphia presented this topic. The study was based upon the chemotherapeutics of tuberculosis. Experiments to test practical measures for increasing resistance by sera, vaccines, or chemotherapy depended upon satisfactory control of experimental material; if not obtained results could not be computed. Bovine experiments were reliable, that is human tuberculosis could be injected into cattle and the resistance measured. With guinea pigs, however, it was found that when a large number of animals were used there was an enormous amount of variation. In the Bureau of Animal Industry careful experiments had been made with breeding of guinea pigs, in regard to resistance and other characteristics. Sewell Wright started a stock in 1906, which since then had been carefully studied as to the effects of inbreeding in 23 pairs of guinea pigs, which had reached the 15th generation of inbreeding. There was a decline in vigor in all respects. Crossing the inbred animals increased the vigor. Comparison was made of different inbred families with the others. One family was more vigorous than the others and there were differences in the kinds of vigor. As regards resistance to tuberculosis, the characters were the same. Sex it was found, made no difference. Age, and weight at weaning made very slight difference in favor of the older and heavier animals. Inbreeding was found to make much more difference than weight and sex. The loss of vigor in a certain family was measured in cross breeds with half-blood, with quarter-blood, and with no blood, of a stock. Cross-breeding promoted vigor. In regard to susceptibility in families 7 per cent. was found due to age and weight; 30 per cent. due to heredity; 60 per cent. due to unknown causes. Animals injected intraperitoneally died much more rapidly than those injected subcutaneously. The size and frequency of litter, and the percentage of young born alive was taken into consideration in computing vigor of stock.

Dr. GEORGE KOBER of Washington, D. C., said that this study of Dr. Lewis recalled to his mind the remarkably large percentage of cases of tuberculosis during the war, in the Southwestern States, which was three times that of the average for the Eastern States. There could scarcely be any other interpretation than that of heredity. This could be explained by the fact that many of the families of these young men or their parents had gone out West for tuberculosis, and one was now dealing with the factor of hereditary predisposition to the disease in the offspring of persons who had migrated to those States in search of health. Certain vulnerable anatomical elements had been handed down from the parents to the children. In 1892, Dr. Kober said he had called the attention of the Health Conference to the fact that there was considerable danger in inviting too many tuberculous individuals to the health resorts. Such persons were apt to settle and perpetuate tuberculous offspring or those predisposed to tuberculosis.

Dr. AUGUSTUS WADSWORTH of Albany, N. Y., said that there was apt to be a confusion of the terms "immunity" and "resistance" in expressing susceptibility to infection. His ideas had been considerably cleared by differentiating resistance due to the strength of the person in recovering from infection, to the resistance which prevented cases of the infection. If one considered the body tissues in the light of favorable or unfavorable media, or as susceptible to the poisonous substances of the bacteria, one got a clearer conception than by the use of the term resistance. It was difficult to conceive of resistance to bacterial infection in that sense. There were two points to be considered: (1) the parasitic activities of the organism growing in the body, and (2) the toxic action of the organism. The disease reaction was the reaction to the injury by the poisons associated with the toxicity of the organism. In tuberculosis, the capacity for growing and continuing to grow was so marked and the toxic activity was so slight, that it gave one a clearer conception of tuberculosis to eliminate the term resistance. In considering susceptibility one must think of the factors that made the body a favorable or unfavorable medium for recovery.

Dr. GERALD WEBB of Colorado Springs asked if they tested animals of other species. He said that mice were susceptible to certain organisms.

Dr. S. S. COHEN of Philadelphia asked if the writers of the paper had made any accurate studies of the resistant animals. This paper suggested that the saying that a man must carefully select his ancestors, bore a good deal of truth. If the guinea pig had carefully selected his ancestors, what had he gained by it in physiological structure? This had been recognized in human beings and attempts at classification had been made. His own observations had led him to believe that lessened susceptibility and greater capacity for recovery were both connected with increased activity of the endocrinal system, especially that of the thyroid gland. Could not such studies be undertaken in these inbreeding experiments on animals?

Dr. PAUL LEWIS, in closing, in answer to Dr. Wadsworth said that he saw no need to complicate the terminology. He did not know whether there was a difference between resistance to toxicity and resistance to bacterial growth. They had perhaps partly interpreted that problem. The first inoculations were intraperitoneal and the experiments were finished in 35 days. In another set of animals the inoculations were made subcutaneously. The disease lasted much longer. The fact that the type of resistance was exactly the same made one think that probably the factors of resistance which were active were active throughout the course of the

infection, rather than in the first days of the inoculation. Later analysis might bring out some difference. As regards the multiplication of these animals this was in itself a task and many details were yet to be studied; but they felt that for the first time there had been a measurable element worked out, that was, that there were families in which a difference could be calculated and expressed in definite terms. Thus it might be able to express dosage in terms of resistance according to a mathematical scale. From the point of view of tuberculosis experimentation, this represented an advance. In regard to the application to human pathology, one would have to go very slowly in carrying over results into the field of human pathology, but it was hoped that these experiments would lead in that direction some day.

Dr. SEWELL WRIGHT said that in some similar experiments in removing part of the thyroid and adrenal gland there was no difference in infection to tuberculosis in the experimental animals. There was hyperplasia in the parts of the organs left but that was the only result observed.

A Study of the Preparation of Antigens from Cultures of the Tubercle Bacillus for the Complement-Fixation Test.—Dr. AUGUSTUS WADSWORTH of Albany, N. Y., made this presentation. He said that the complement fixation test needed satisfactory methods of preparing and standardizing the antigens so that the infection at different stages could be determined. The complement-fixation test as used in the laboratory for determining different species of bacteria was not of very much use at the bedside clinically. It was a difficult test in respect to diagnosis and interpretation. Antigens from spirochetes were not satisfactory, but there were definite results from syphilitic tissues. In regard to tubercle bacillus antigens, three strains were used: (1) bovine; (2) virulent human; (3) non-virulent human, incubated at 35.5° C. The results did not differ from those of other investigators. Studies were made on experimental infections and carried out with hemolytic organisms. It was found that aqueous extracts gave satisfactory antigens. Next it was necessary to get immune sera to those strains which could be measured against the antigens. Cows and guinea pigs were tried without success, but an immune serum was obtained from the horse. Filtrates were found to be unsatisfactory for antigens; if dialyzed they lost their anticomplementary characteristics. The broth filtrate was tested to see what the injected substance was; it was all removed by animal charcoal, but could not be recovered from the charcoal; 3/10,000 c.c. fixed 2 units of immune serum.

Dr. PAUL LEWIS of Philadelphia said that he would like to ask whether Dr. Wadsworth had found any indication as to whether the alcoholic extract comprised the whole of the antigenic character of the tubercle bacillus, or was there anything in the residue which was injected. There was a difference between antigens of bacterial suspension and the alcohol. Four hours primary incubation was necessary to develop the full antigenic value of the bacterial suspension. Was this the case with the alcoholic extract? He thought it usually developed its value in half an hour.

Dr. WADSWORTH, in closing, said that their original plan was laid out to determine that point and others, but he did not feel as yet that they understood the full significance of this work. They were just at the beginning of the investigation as regarded physical conditions and further facts might clear up that question. The filtrate after dialyzing became active without any extraction. Simple removal of the dialyzable factor removed that anticomplementary power. In the tests made by them the complement treated that way acted in a similarly specific manner to the antigen prepared from alcoholic extract after adsorption from globulin. After diluting the alcoholic extract 1:10, the action was similar to that of the filtrate.

Irritability and Stimulation.—Dr. S. J. MELTZER of New York presented this paper. He said that irritability was the characteristic element of life. In the times of Halle and Glucke, in the 17th century, great importance was attached to motion, and irritability was considered identical with motion. John Brown, Johannes Mueller, Virchow, and later Verworn developed the theory of irritability as essential to life. Medicine, however, did not understand irritability in that sense, but as something abnormal or antagonistic to life. Medicine considered stimulation as important to the conditions of life, but physiologists considered it merely as coincident. A dualistic conception of the phenomena of life had been worked out by some physiologists. At the International Congress in London in 1913, Sherrington advanced the eclectic theory, Verworn the monistic theory, and Meltzer the dualistic conception. Life was conceived as comprising three phenomena—motion, secretion, and sensation. No life could exist without some living tissue being in action, and any living function must be continually in action. The physiologist must consider why the organism was in action, and it was also necessary to remember that there were some forms of life which appeared to have no action at all. The arrest of conditions did not always mean that tissue was not animate, but that it was under the condition of inhibition. This explained the dualistic theory, which was not dogmatic. Anything which was acting under a certain state of life might be called a stimulus, but a stimulus might not be increase of activity; it might be a decrease. Either stimulation or inhibition might be produced. The latter meant life, just as much as the former. In contraction living substances were used up, and the body would go to pieces if it were not for the fact that during inhibition living substances were again accumulated. Inhibition was the condition which made activity successful. During extension inhibition took place in the flexors. Sherrington spoke of this as "reciprocal innervation." The wave of inhibition must run ahead of the wave of contractions, just as in the railroad the signal went ahead to indicate that the road was free.

The Production of Generalized Syphilis in the Rabbit by Local Inoculation.—Drs. WADE H. BROWN and LOUISE PEARCE of New York made this presentation. These studies were made upon rabbits. Lesions upon the skin in the experimental animals were quite rare. In 126 cases the animals showed lesions at the site of inoculation. There was a very marked reaction in the testicles and scrotum, which it was thought might inhibit the production of lesions elsewhere. Tests were made to determine whether all the animals had a generalized reaction following local inoculation. Lymph nodes from infected rabbits were implanted into the testicles of normal animals and infection was produced with these excised lymph nodes. The organism was recovered from the heart's blood in from 7 to 100 days after implantation. This proved that dissemination of the organism occurred. An attempt was made to determine the protective effect of local lesions against generalized lesions. An amputation of the testicle was made after 48 hours, but general infection supervened. It was found that under certain conditions where inoculations were made with strains of *Treponema pallidum* and where the lesions were controlled, the animals might develop generalized syphilis.

Dr. HOMER F. SWIFT of New York said that this was a very interesting and important contribution. This experimental work had a bearing on the treatment of human syphilis. It had been noted in the army work that when the drug was used to cure the lesion but not to kill the spirochetes, the reactions were more severe than if the syphilis had been allowed to run its course. This was the first time such a conclusion had been demonstrated in a convincing manner. A note of warning should be sounded: this demonstration of the generalization of the spirochete so early might have something to do with letting down the use of prophylactic measures after exposure. Local prophylaxis was effective for a certain number of hours. This type of inoculation was different from that which occurred in human syphilis. This work might explain the mode of transmission of the virus into the deeper organs.

Dr. GEORGE BLUMER of New Haven said that there had been periods when attempts had been made to prevent syphilis by excision of the primary sore. In Dr. Brown's work the excision of the chancre led to unusually rapid dissemination of the disease.

Dr. BROWN, in closing, said that the status of the disease in the human being as regards magnitude of the primary lesion and the generalized reaction was different, but generalization could occur in the human

being as early as in the rabbit. If the cases were not treated following excision they got a more pronounced reaction. That, however, did not contraindicate excision of the chancre. In rabbits the local lesion had a necrotic center in which the spirochetes might survive. In cases well treated there was a chancre redux, but in human cases he did not think that excision of the chancre would prevent generalization. The organism in experimental work could be recovered from the lymph nodes and from the general circulation long before they could excise the chancre. In regard to treatment of early cases, although generalization might have taken place, lesions had not developed. The symptoms had to be treated on account of the pathological nature of the object one was trying to overcome.

Eventration of the Diaphragm, with Report of a Case.—Drs. ELMER H. FUNK and WILLIS F. MANGES of Philadelphia made this presentation. They reported 50 cases in the literature. The diagnosis could now be made by the *x*-ray. There was a typical elevation of the diaphragm. It was often associated with other anomalies and was probably congenital. In one case seen, a white female, aged 39, there was pain in the upper abdomen and back and shortness of breath. It was thought that there was a hydro-pneumothorax, but a needle inserted in the chest found nothing. The *x*-ray showed a high position of the diaphragm. The heart was displaced. The lungs were free from disease. There was widening of the subcostal angle on inspiration. The abnormality was not reflected in the external symmetry of the chest.

Dr. J. RAMSAY HUNT of New York said that one should take into consideration that these structural changes were associated with striated muscle fibre. The diaphragm was innervated by the sympathetic system. If the vagus nerve was cut paralysis was produced but there was preservation of tonus; if the splanchic were cut tonus was lost but movement was preserved.

Dr. C. F. HOOVER of Cleveland said that the observation of increased movement of the costal margin on the affected side would be of service in the differentiation between hernia and eventration. In hernia there was a large portion of the stomach in the thorax and the movement of the costal margin was not modified. One could stuff any quantity of viscera in the diaphragm but the movements of the costal margin were not changed. There might be dullness in the left thorax due to the retraction of the lung. In the other case there would not be elevation pitch of the percussion sounds.

Dr. S. J. MELTZER of New York asked if the Libman phenomena were observed. That would give information as to where the diaphragm was.

Dr FUNK, in closing, said that pathological studies were made on 20 reported cases but in none of these had any work been done on the innervation. He could pay a tribute to the value of the work of Dr. Hoover on the diaphragm. He was impressed with the necessity of investigating the movements of the costal margin. The Libman phenomena were absent in these patients.

The Dietetic Treatment of Gastric Ulcer Based on Experimental Studies.—Dr. MARTIN E. REHFUSS of Philadelphia read this paper. He said that this work on the gastric digestion was done at the Jefferson Medical College. He could not say what was the etiology of the ulcer, but acidity of the gastric contents had to do with the chronicity of the ulcer. It might not cause it, but it would prolong it. These studies were undertaken over a long period of time and with different food stuffs. The results seriously undermined the modern conception of treatment of ulcer. Three types of normal stomach were observed in the 100 students examined: (1) hypersecretive, high acid, 100 per cent. or over; (2) mesosecretive type; (3) a low secretive type. Chemical secretion was found to continue all the time, and psychic secretion at varying times. There was an average total acid of 30 and free acid of 18-20. This was between digestive phases and showed increase of trypsin. His studies had led Dr. Rehfuss to incline to the bacterial causation of gastric ulcer. He found very little difference between the unobstructed stomach and the normal stomach. Some cases showed reduction in acid. In ulcer cases there was disturbance of the interdigestive phase. The reactions to food showed that the present conceptions as to diet were erroneous. With eggs there was a total acidity of 80 and with beef 120. It was essential to thoroughly understand normal variations before attempting to interpret pathological studies. There was really no such thing as a pathognomonic gastric curve, with the exception perhaps of the regurgitation of blood and bile. High acid curves and low acid curves had a similar appearance, the difference being due to varying conditions. Milk, meat, fish and egg were found to be acid producers, while vegetables produced little acid. What were the conclusions that could be drawn from these studies? It would seem that prolongation of supervision was desirable. As to nutrition, 1,500 calories could be given by Murphy drip. Sippey's methods could be used to control free acid. Bread, cereals and vegetables could be given. If it was found that the eating of neat was the occasion of a high degree of acidity, then people should be kept off meat, not six weeks, but six months.

Dr. G. H. WHIPPLE of San Francisco said that by concentrating the *x*-ray over the abdomen of the dog, one could produce ulcers that would not heal and would perforate. This could not be a question of acid but a question of the type of injury to the mucous membrane. Whether that was a factor in human ulcers he did not know.

Dr. B. W. SIPPEY of Chicago said that he was interested in Dr. Rehfuss' report. He had had considerable experience in controlling acid. Bismuth was formerly used but now he found that calcium carbonate acted to prolong the control of free acid. Some of the factors in causation of ulcers were unknown. Hydrochloric acid seemed to have a devitalizing action of the protoplasm and did damage to the cells. To control peptic activity, one must control free acid.

Dr. M. E. REHFUSS of Philadelphia, in closing, said that in experimental animals work had been done by producing ulceration with various forms of toxins, but if one constantly neutralized the stomach of the animal during injection of the toxin, one could inhibit the formation of ulcer. The acid had a secondary character, but the toxin the primary role. The question was one of local toxicity. A careful study must be made to control foods that produced high acid. Milk curds were difficult of digestion and did not completely reduce free acid without neutralization. Oils and fats caused a low secretion of the stomach. There was, however, no single food stuff, the speaker said, that was not followed by a higher rate of secretion than that of the normal stomach.

Blood Regeneration After Simple Anema as Influenced by Various Dietary Factors.—Dr. G. H. WHIPPLE of San Francisco presented this communication. It was found that the pigment volume was blood volume times the percentage of hemoglobin. In an animal bled till the pigment was reduced to a level of 40 per cent below normal, followed by the institution of a meat diet, the pigment level normalized within 4 weeks. With milk diet the 40 per cent level persisted. A fasting animal with access to water could reproduce the hemoglobin. showing that the body could reorganize its elements into hemoglobin. Spinach was found to return the level of hemoglobin to normal and keep it there. Milk gave the minimum regeneration. Cooked liver and cooked beef heart produced the best regeneration. Blaud's pills had no effect.

Dr. HARLOW BROOKS of New York said that meat being a natural diet for a dog might be supposed to have more influence in those animals in improving the hemoglobin.

Dr. S. J. MELTZER of New York said that when he entered into experimentation he did so from the human side. He did not know any drug that acted so well in human chlorosis as Blaud's pills, nor one that had more specific action, unless it were 606.

Dr. G. H. WHIPPLE said that the experiments were done upon dogs and he left the interpretation of results to the internists. Dogs were omniverous animals, and were used to thrive on a mixed diet. He could not venture to interpret these results as regards human chlorosis. The animals were under controlled conditions that could not be applied to patients and it was up to the clinicians to prove that the drugs they gave had effect.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Florida State Board of Medical Examiners.

Jacksonville, June 14, 1920.

ANATOMY.

1. Name branches of subclavian artery.
2. What arteries, muscles, and nerves would be severed in a cross section at the middle of the humerus?
3. Describe the portal system.
4. Describe the thyroid gland.
5. Describe origin and distribution of optic nerve.
6. Give origin and distribution of median nerve.
7. What muscles form the tendo Achillis, and where is the tendon inserted?
8. Name the bones of the head.
9. Describe one of the vertebrae.
10. Give the surgical anatomy of femoral hernia.

PHYSIOLOGY.

1. Name, locate, and give functions of ductless glands.
2. Blood. Give specific gravity, reaction, and quantity of blood in the body. How is it renewed after hemorrhage?
3. Locate and describe Peyer's glands.
4. Give the digestive secretions, their active principles, and how they act on food.
5. What is the physiologic function of the liver?
6. Describe osmosis, and give an example.
7. What should be the proportion of nitrogenous and non-nitrogenous elements in the food?
8. Give the functions of the kidney. Is it constant and equal in both kidneys? What happens where one is removed?
9. Define: Afferent, efferent, trophic, inhibitory, motor, and vasomotor nerve fibres.
10. Define a reflex act, and what are the essentials necessary to produce same?

CHEMISTRY.

1. Define chemistry. How is it divided?
2. How many elements are there, and by what simple means are they represented?
3. Give chemical formula of (*a*) water, (*b*) nitric acid, (*c*) sulphuric acid, (*d*) hydrochloric acid.
4. Describe the chemical process (*a*) when iron rusts, (*b*) when wood burns, (*c*) when silver is tarnished by coal gas.
5. Mention six elementary substances commonly used in medicine in their pure state.
6. What is (*a*) a normal salt, (*b*) an acid salt, (*c*) a double salt, and give an example of each.
7. What are chlorides? Bromides? Give an example of each.
8. What are the essential elements of all acids?
9. Explain the terms (*a*) solutions, (*b*) precipitates, (*c*) incompatibles.
10. What is a chemical reagent?

MATERIA MEDICA AND THERAPEUTICS.

(Answer *ten* questions only.)

1. What are the advantages of ether as an anesthetic? Contraindications for its use?
2. What is "cumulative effect" of drugs? Name one drug which has this tendency, and the symptoms.
3. Give therapeutic use of caffeine.
4. Give therapeutic indication for bromides, and effects from long continued use.
5. Name ten drugs most frequently prescribed by you, giving maximum and minimum dose, and length of time between each dose. Write ℞ containing two or more drugs.
6. Name the nine most used preparations of mercury and give principal therapeutic uses.
7. What are the contraindications for use of quinine?
8. Outline your treatment and diet of typhoid fever.
9. Give treatment of angina pectoris.
10. Give treatment of hemoptysis.
11. Hypodermoclysis. Describe method of administration. Give disease and conditions in which you consider it a therapeutic agent.
12. Outline treatment for care of articular rheumatism (acute is meant here).
13. Name five drugs most frequently used by you hypodermically, dose and indications for use.
14. Give dose and indications for use of thyroid extract.
15. Give dose, best way of administration, and medical uses of adrenalin.

ANSWERS.

ANATOMY.

1. *The branches of the subclavian artery*, are: Vertebral, thyroid, axis, internal mammary, and superior intercostal.

2. In a cross section at middle of humerus, will be severed: *Arteries:* Brachial, superior profunda, inferior profunda; *Muscles:* Biceps, brachialis anticus, coracobrachialis, triceps; *Nerves:* Median, ulnar, musculospiral, internal cutaneous, musculocutaneous.

3. *The portal system.*—The veins of the portal system collect the blood from the digestive tract. They form a trunk, the *vena portæ*, which enters the liver and breaks up into small branches in its substance. The following veins form the portal system:

Inferior mesenteric: drains rectum, sigmoid, flexure, and descending colon. It lies to the left of its artery, and passing behind transverse part of the duodenum and the pancreas, and over left kidney, opens into the splenic vein. (The hemorrhoidal branches inosculate with the hemorrhoidal branches of the internal iliac.)

Superior mesenteric: drains small intestines, cecum, ascending and descending colon. It passes upwards in front and to right of superior mesenteric artery, in front of transverse part of duodenum, and behind neck of pancreas joins the splenic vein at the upper border of the pancreas to form the portal vein.

Splenic: commences in five or six branches in hilum of spleen; these unite to form a trunk which passes below splenic artery behind upper border of pancreas from left to right, and in front of aorta; joins superior mesenteric at a right angle.

The gastric or coronary: a large vein accompanying coronary artery from right to left along lesser curvature of stomach to cardia, where it reaches esophageal tributaries, and, passing to right behind lesser sac, opens into the vena portæ.—(*Aids to Anatomy.*)

The *portal vein* is formed by the union of the splenic and superior mesenteric veins in front of the right crus of diaphragm and inferior vena cava, and behind the neck of the pancreas. Passes up behind first part of duodenum and then between the layers of the small omentum, behind and between the common bile-duct and hepatic artery, the duct being placed on the right and artery on the left, to transverse fissure of liver, where it divides into right and left branches to corresponding lobes, and also gives an offset to the Spigelian lobe. Connected with the branch to the left lobe are in front the *obliterated umbilical vein* and behind the *ductus venosus*, the remains of a fetal connection with the inferior vena cava.—(*Aids to Anatomy.*)

4. The *thyroid gland* is situated on the sides and in front of the upper part of the trachea, and extends upward on each side of the larynx. The *thyroid gland* consists of two lateral lobes and an isthmus: it is situated at the front and sides of the neck. The lobes extend from about the middle of the thyroid cartilage to the fifth or sixth tracheal ring; the isthmus generally covers the second and third tracheal rings. The lobes measure about 2x1¼x¾ inches; the gland usually weighs about one ounce. *Blood supply:* Superior and inferior thyroid arteries, with thyreoidea ima; and superior middle, and inferior thyroid veins. *Nerve supply:* Branches from the inferior laryngeal nerve, and from the middle and inferior cervical ganglia of the sympathetic.

5. Optic Nerve.—*Origin:* From optic tract, which arises by two roots, the outer coming from the external geniculate body, optic thalamus, and superior quadrigeminal body; and the inner from the internal geniculate body. *Distribution:* It is expanded to form the retina, on the surface of which the images of external objects are received.

6. Median Nerve—*Origin:* It arises by two roots,

one from the outer cord and the other from the inner cord of the brachial plexus. *Distribution:* To all the superficial muscles of the front of the forearm except the flexor carpi ulnaris; to all the deep muscles of the front of the forearm except the inner half of the flexor profundus digitorum; to the skin over the radial side of the palm of the hand, over the front of the thumb, index, middle and half of ring fingers, and over parts of the dorsal aspect of the same fingers; also to the first two lumbrical muscles, and to the outer group of short muscles of the thumb.

7. The *Tendo Achillis* is formed by the gastrocnemius and soleus muscles. The tendon is inserted into the posterior part of the os calcis.

8. The *bones of the head*, are: Occipital, frontal, two parietals, two temporals, sphenoid, ethmoid, two lacrymals, two malars, two nasals, two palates, two superior maxillary, two inferior turbinates, vomer, and inferior maxillary.

9. *The fourth cervical vertebra* has a small, transversely elongated body, with no facets for ribs; the laminæ are long and slender; the spinous process is short, nearly horizontal, and bifid; the transverse processes are short, and contain a foramen for the veretebral artery; the superior articular process is directed upward and slightly backward; the inferior articular process is directed downward and slightly forward; the spinal foramen is large and triangular.

10. *Femoral hernia* leaves the abdomen through the femoral ring and descends into the femoral canal; this canal is funnel-shaped, is about half an inch in length, and ends at the saphenous opening. Femoral hernia is always *acquired*, and has a sac. Its course is first vertical, then forward, then upward over Poupart's ligament. Its coverings, from without inward, are: Skin, superficial fascia, cribiform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum. The neck of the hernia is situated at the femoral ring; to its outer side lies the femoral vein, and to its inner side is Gimbernat's ligament; in front of it is Poupart's ligament, and behind it are the pubis, the Pectineus, and the pubic portion of the fascia lata. In the immediate neighborhood of the femoral ring are: Anteriorly, the communicating branch between the deep epigastric and the obturator arteries; externally, the femoral vein and deep epigastric vessels; superiorly, the spermatic cord (or round ligament) and the deep epigastric vessels.

PHYSIOLOGY.

1. *Ductless Glands.*—(1) The *spleen;* situated in the back part of the left hypochondriac and epigastric regions, being covered by the ninth, tenth, and eleventh ribs on the left side. (2) The *thyroid;* situated on the sides and in front of the upper part of the trachea, and extending upward on each side of the larynx. (3) The *suprarenals;* situated in the back part of the abdominal cavity, behind the peritoneum, one on the upper extremity of each kidney, and slightly also on the inner and anterior surfaces. (4) The *carotid gland:* situated generally in the carotid bifurcation. (5) The *thymus;* situated in neck, and superior mediastinum, up to lower border of thyroid. (6) The *coccygeal gland*, at the tip of the coccyx. (7) The *parathyroids;* situated near the thyroid, on the posterior surface, near the junction of the pharynx and esophagus; but they are variable in position. (8) The *pituitary body* is situated on the floor of the skull, on the sella turcica of the sphenoid bone.

The function of the spleen: The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The function of the thyroid is not definitely settled: (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances and (3) it produces an internal secretion.

The function of the thymus is not settled; it is said: (1) to be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The function of the suprarenals is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body. They aid in maintaining blood-pressure, and in keeping up nutrition and body strength.

Function of the pituitary gland: "The *anterior* lobe is concerned with the process of growth, hypertrophy leading to overgrowth of the skeleton, and partial removal to failure of development of the body as a whole and of the sexual glands. Extracts of the *posterior* lobe, when injected into an animal, have a direct action on plain muscle all over the body; they cause constriction of the arterioles and a rise of blood pressure, contraction of the muscular coats of the digestive tract and of the bronchioles, and contraction of the uterus. The extracts also produce an increased flow of urine, which was at first attributed to the presence of a substance having a specific effect upon the renal cells; it is probable, however, that the diuretic effect is merely an indirect result of the more rapid flow of blood through the kidney which follows the injection of the extract. Extracts of the posterior lobe increase the secretion of milk, and after the injection a larger amount of milk is formed by the animal in the course of twenty-four hours."—(Bainbridge and Menzies' *Essentials of Physiology.*)

2. BLOOD.—*Specific gravity* is about 1055. *Reaction* is alkaline. *Quantity in body*, is about one-twentieth of the body weight.

Regeneration of blood after a hemorrhage: "If the bleeding does not go on to death the blood is restored by absorption from the tissues or from the food taken in; the first to be absorbed being the serum sanguinis, with the dissolved salts, and then the albumen. A longer time is required to form new red blood-corpuscles. Regenerated blood is at first abnormally watery and poor in cells. As a result of the greater flow of lymph into the blood the number of white blood-corpuscles is greatly increased, and then their number falls off; the red blood-corpuscles again attain their usual number, and the composition of the blood gradually returns to the normal. We do not as yet know certainly how the restoration of the red blood-corpuscles takes place. The most generally accepted view is that colorless corpuscles are being constantly formed in the lymph glands, in the spleen, in the bone marrow, and in the liver, and a certain number of these colorless corpuscles change into the red disks."—(Tillmann's *Surgery.*)

3. *Peyer's patches* are collections of lymphoid nodules found in the mucous membrane of the lower part of the small intestine (the ileum).

4.

DIGESTIVE SECRETIONS.	ACTIVE PRINCIPLES.	FUNCTIONS.
Salivary....	Ptyalin.	Changes starches into dextrin and sugar.
Gastric.....	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic..	Trypsin.	Changes proteids into proteoses and peptones and afterwards decomposes them into polypeptides and amino-acids; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.
Intestinal...	Invertin.	Converts maltose into glucose.

5. *Functions of the liver* are: The formation of bile,

urea, uric acid, creatinine, and antithrombin; the production of heat; the conversion of hemoglobin into bile pigment, and the glycogenic function (formation and storage of glycogen).

6. *Osmosis:* "If two different liquids are separated from each other by a porous partition, a current sets in from each liquid to the other. The strength of these currents depends on the facility with which the liquids are imbibed by the partition and the tendency the two fluids have to mix with each other; the fluid which soaks most rapidly into the partition—*i.e.*, that which wets it most readily—passes through it most rapidly. If a bladder be filled with syrup and immersed in water, the water will pass into the bladder more rapidly than the syrup passes out, and may so far raise the pressure in the interior of the bladder as to burst it. The water is said to pass into the bladder by endosmosis, and the syrup to pass out by exosmosis. Dialysis differs from osmosis in this: In dialysis a crystalloid in solution passes into a fluid, which contains a smaller quantity of the crystalloid; osmosis occurs at the same time, but the phenomena are quite distinct. The law of osmosis deals only with the currents of liquid. The blood-vessels of the alimentary canal absorb fluids by osmosis. The plasma has only a very slight tendency to pass out of the vessels, while the liquids contained in the alimentary canal pass into the blood with great readiness. The *laws of osmosis* are: (1) The liquids must be of different densities. (2) They must be capable of mixing with each other. (3) The membrane must be permeable to at least one of the liquids. (4) The current produced is greater the greater the tendency of the liquid to permeate the membrane—the greater current is spoken of as endosmosis, the lesser as exosmosis. All these conditions exist between the blood and the fluids with which the blood-vessels are surrounded, and the fluids outside the vessels pass into them more readily than the blood plasma escapes. Endosmosis usually occurs from a lower to a higher pressure."—(*Aids to Physiology.*)

Examples of osmosis in the human economy: "In the body we have aqueous solutions of various substances separated from one another by membranes. Thus we have the endothelial walls of the capillaries separating the blood from the lymph; we have the epithelial walls of the kidney tubules separating the blood and lymph from the urine; we have similar epithelium in all secreting glands; and we have the wall of the alimentary canal separating the digested food from the blood vessels and lacteals."—(Halliburton's *Physiology.*)

7. The necessary proportion of the various foods is given as protein about 17 per cent., fat about 8 or 9 per cent., and carbohydrate about 74 per cent.

8. The *functions of the kidneys* are: (1) To secrete (or excrete) urine; (2) to regulate the reaction of the urine; (3) the formation of hippuric acid; (4) regulation of the composition of the blood plasma by excretion of abnormal or toxic substances; and (5) the production of an internal secretion.

The secretion of the urine is not necessarily constant and equal in each kidney.

If one kidney is removed the other hypertrophies and performs the functions of both.

9. An *afferent* nerve fiber is one that conducts nerve impulses from the periphery towards the brain or cord.

An *efferent* nerve fiber is one that conducts nerve impulses away from the brain or cord, and towards the periphery.

A *trophic* nerve fiber is one that nourishes a tissue or organ or part of the body.

An *inhibitory* nerve fiber is one which conveys a nerve impulse which results in the lessened activity of a part.

A *motor* nerve fiber is one which causes contraction of a muscle.

A *vasomotor* nerve fiber is one which conveys nerve impulses to the muscular coat of a blood vessel.

10. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

CHEMISTRY.

1. *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing such changes. It is generally divided into *Inorganic* Chemistry and *Organic* Chemistry.

2. There are about eighty-three elements. They are represented by *Symbols;* each symbol denoting one atom of an element.

3. *Water*, H_2O; *Nitric acid*, HNO_3; *Sulphuric acid*, H_2SO_4; *Hydrochloric acid*, HCl.

4. *When iron rusts*, oxygen aided by water attacks the iron and forms the oxide and hydroxide of iron in varying proportions.

When wood burns, the cellulose takes up oxygen from the air, and splits up into carbon dioxide and water.

When silver is tarnished by coal gas, the hydrogen sulphide which exists as an impurity in coal gas, attacks the silver, and produces silver sulphide.

5. *Six elementary substances commonly used in medicine in their pure state:* Oxygen, sulphur, iodine, carbon, mercury, and phosphorus.

6. *A normal salt* results when all of the replaceable hydrogen of the acid has been displaced by the basylous element; thus K_2SO_4.

An acid salt results when only part of the replaceable hydrogen of the acid has been displaced by the basylous element; thus $KHSO_4$.

Double salts are such as are formed by the substitution of two different elements for the replaceable hydrogen of the acid; thus $NaKSO_4$.

7. *Chlorides* are salts of hydrochloric acid; thus KCl, NaCl.

Bromides are salts of hydrobromic acid; thus KBr, NaBr.

8. *Hydrogen* is the essential element of all acids. Oxygen is also present in all acids except the hydracids.

9. A *Solution* is a homogeneous mixture of a substance with a liquid. If solutions of two salts are mixed, and by double decomposition an insoluble salt can be formed, such double decomposition will take place and the insoluble salt will be formed; this insoluble compound separates, from the solution as a *precipitate*. Substances are said to be chemically *incompatible* if on being mixed together they undergo chemical decomposition, or form an explosive compound.

10. A *chemical reagent* is any substance used to bring about a chemical reaction.

MATERIA MEDICA AND THERAPEUTICS.

1. *Ether* "is the best and least dangerous general anesthetic in the hands of one with little experience, likewise in the hands of the specialist in anesthesia when, as is the case in most of the major operations of surgery, the patient is to be completely relaxed, hence, under these circumstances, should always be employed unless there are distinct contraindications. The most important *contraindication* to ether is *inflammation of some portion of the respiratory apparatus*, owing to its irritating action upon mucous membranes. Of secondary importance, and by no means absolute, are marked *arteriosclerosis*, because of the danger of vascular rupture from the struggling incident to the etherization; *disease of the kidneys* (many authors believe chloroform to be more irritating to the kidneys than ether; in these cases nitrous oxide and oxygen or local anesthesia should be employed whenever possible); *operations about the nose or mouth*, in which the anesthetic can be applied intermittently only, and in which chloroform, being more powerful, will better maintain

anesthesia (this contraindication ceases to exist if one of the insufflation methods is employed); operations in which the *actual cautery* may be needed in the region of the mouth, owing to the inflammability of ether, although it may be used in these cases, if the precaution is first taken to remove the anesthetic and fan away the fumes; and operations performed in the presence of an *exposed artificial light*, although, since ether vapor is heavier than air and descends, the danger in these cases is obviated by placing the light several feet above the level of the patient's head. Ether should not be administered in the presence of fire in an open grate or stove."—(Stewart's *Surgery*).

2. *Cumulative Action.*—"This is the property which some drugs have, after they have been given for a certain length of time, of producing a severe and more or less sudden effect. It is probably due in most instances to an accumulation of the drug in the tissues, excretion, for one reason or another, being less rapid than absorption. In some cases, however, it may depend upon irregular absorption, a large quantity of the drug suddenly entering the circulation from the alimentary canal, where, owing to some accidental condition, there has been an undue accumulation."

"The uninterrupted use of digitalis in full doses is some times followed by the sudden appearance of toxic symptoms; this untoward effect seems to be due to the *cumulative action* of the drug, and is especially liable to occur when there is no diuretic effect, and after the removal of serous effusions by paracentesis. In the first instance elimination is interfered with, and in the second, absorption is effected with undue rapidity. The earliest manifestations of this accident are usually irregularity of pulse, precordial distress, and the appearance of the heart-beats in couples, the first of which only can be detected at the wrist. When a prolonged use of the remedy is required, it should be suspended at intervals for a definite period, so as to allow of complete elimination."—(Stevens' *Modern Materia Medica.*)

3. *Therapeutic uses of caffeine.* "It is employed as a prompt cardiac stimulant, but its chief utility in heart affections is in cases attended with dropsy, where by its diuretic action it often proves highly efficacious. Within certain limitations it is a diuretic of value, though not as reliable as theobromine, and small doses are more efficient as regards the kidneys than large ones. It is contraindicated in acute renal inflammation. As a sitmulant to the central nervous system, and especially to the respiratory centre, it is of great service in cases of poisoning by opium or alcohol. It is also used in hypochondriasis, neurasthenia, nervous headaches, neuralgia, typhoid and other fevers, diarrheal affections, especially when dependent on agencies affecting the nervous system, asthmatic paroxysms, and pneumonia or pulmonary congestion with weak heart."—(Wilcox's *Materia Medica.*)

4. *Bromides. Therapeutic indications.* "The bromides constitute our most valuable remedy for epilepsy, but as they must be continued for a long period, every effort should be made to minimize their injurious effects upon the system. They are much used also, either alone or in combination with other drugs, in the treatment of insomnia, nervousness, hysteria, neuralgia, migraine, delirium tremens, seasickness, seminal emissions, nymphomania, and various forms of convulsions. Except in cases of epilepsy they should not, as a rule, be given continuously very long, on account of the danger of the patient's contracting the bromide habit."—(Wilcox's *Materia Medica.*)

Their *long-continued use* results in a condition known as *bromism.* This condition is characterized by headache, coldness of the extremities, feebleness of heart-action, somnolence, anorexia, apathy, pallor of the skin, an acne eruption, and lowered sensibility of the fauces. There may be loss of sexual power, with atrophy of the testes and mammary glands.

5. *Ten frequently used drugs.—Potassium iodide*, 5 to 30 grains; *Calomel*, 1/10 to 5 grains: *Tincture of aconite*, 1 to 5 minims; *Apomorphine hydrochloride*, 1/12 to 1-6 grain: *Morphine sulphate*, ⅛ to ½ grain: *Quinine sulphate*, 1 to 15 grains; *Tincture of digitalis*, 5 to 15 minims; *Sodium salicylate*, 3 to 15 grains; *Amyl nitrite*, 2 to 4 minims, by inhalation; *Oleum ricini*, 4 to 8 drams. The *interval* between doses depends on the purpose for which the drug is given. Ordinarily, from 4 to 8 hours should elapse; but when the desired effect has been obtained no more of the drug should be given.

6.

Nine Preparations of Mercury	Chiefly Indicated in
Ammoniated mercury	Ozœna, psoriasis, tinea, and other skin affections.
Bichloride of mercury.....	Syphilis, anemia, summer diarrhea.
Calomel	Syphilis, biliousness, dropsy, dysentery.
Red oxide of mercury.....	Syphilitic sores, chronic skin diseases.
Yellow oxide of mercury....	Indigestion, syphilitic sores, chronic skin diseases.
Red iodide of mercury.....	Syphilis, acute tonsillitis.
Yellow iodide of mercury...	Chronic Bright's disease, syphilis.
Solution of mercuric nitrate.	Epithelíomata, warts, lupus.
Ointment of mercuric nitrate.	Chronic skin diseases.

7. *Contraindications to the use of quinine:*—Meningitis, acute middle-ear disease, acute inflammation of the genito-urinary tract, and when the patient shows an idiosyncrasy toward the drug.

8. *Treatment of typhoid fever with its principal complications:*—The patient must be in bed, and no medicine given unless indicated. "Give no solid food, or that which would not readily pass through a fine sieve. Milk, if it agrees, albumin-water made from white of egg, beef tea, and chicken broth are the principal foods. Of late some authorities have advocated a light solid diet throughout, but nothing must be given that would increase the risk of perforation. The stools should be daily inspected. If undigested curd is found, milk is being given too often, or the gastric function is impaired. It may then be given with lime water or barley water. Beef tea should be sparingly used, lest it excite diarrhea. Alcohol is required mainly in the later stages, when the typhoid state has set in, and the heart is weak. Many cases do well without it altogether. Other stimulants are strychnine, ammonia, ether, etc.

"If the *diarrhea* becomes excessive give bismuth and opium, or lead acetate and morphia, or an enema of starch and opium. When the motions are very offensive intestinal antiseptics (calomel in small doses, salol, etc.), may be given. They are also useful in meteorism. If *constipation* be troublesome, give enemata. No purgatives should be given after the first week. *Hemorrhage*—opium, lead acetate, or calcium lactate gr. xv every four hours, hypodermic injection of morphine or ergotin, ice-bag to the cecum. *Perforation*—The main chance of recovery lies in early laparotomy and suture of the affected bowel. Every hour lost after the diagnosis is made, and the initial shock has passed off, increases the danger to life. Cases operated on within twenty-four hours may recover; later, recovery is very rare. In anticipation of operation, morphine may be given to relieve pain and diminish peristalsis. *Bed sores*—water-bed, cleanliness, stimulant and antiseptic lotions, dry dressings if the slough is large. *High fever*—quinine and cold baths. The antipyrin group is dangerous to the heart. The stools and urine must be carefully disinfected. During *convalescence* the diet must be increased with the utmost caution, and the possibility of relapse must always be remembered."—(Wheeler and Jack's *Handbook of Medicine.*)

9. *Treatment of angina pectoris:*—"The general treatment is that of chronic myocardial disease. In syphilitic cases specific medication is, of course, indicated. Abstinence from alcohol and tobacco should be strictly observed. The most valuable special remedies, in the order of their efficacy, are the nitrites, iodides, theobromine, and arsenic.

"*The Attack*—No drug is so generally useful as amyl nitrite (3 to 5 minims on a handkerchief). Marked flatulency should be met by the prompt administration of Hoffmann's anodyne or spirit of mint. If the attacks are severe and prolonged morphine (1/3 to ¼ grain) and atropine (1/120 grain) should be given hypodermically. If these remedies fail, recourse should be had to chloroform inhalations. The application

of heat to the precordium is useful. Cardiac depression following the seizures should be combated by strychnine, ammonia, camphor, or ether."—(Stevens' *Practice of Medicine.*)

10. *Treatment of hemoptysis:*—"Unless a large artery is opened, bleeding usually ceases spontaneously, and the patient should be reassured. Absolute rest and quiet, light food given cold, ice to suck and injections of morphine and atropine suffice in the majority of cases. Inhalation of nitrite of amyl is a valuable measure. Ergot raises the intrapulmonary blood-pressure and may do harm. In protracted cases, saline purgatives and aromatic sulphuric acid are indicated. Adrenalin is useless."—(Wheeler and Jack's *Handbook of Medicine.*)

11. "Hypodermoclysis is a method of supplying fluid to the body to replace that lost through excessive purging, as in cholera, or in cases of hemorrhage. Further, it may be used to wash from the body various impurities circulating in the blood and lymph, and to flush the kidneys. In other instances it may be used to supply the body with liquid when the stomach will not permit liquid to be swallowed, as in vomiting, or gastric ulcer, or after abdominal operations. It consists in the introduction into the subcutaneous tissue of normal saline solution, which is rapidly absorbed by the vessels.

"When hypodermoclysis is employed after hemorrhage the results are often extraordinary. It is of great value in the collapse of cholera. The cyanosis decreases rapidly, the pulse improves, and respiration is no longer difficult. Some physicians have used hypodermoclysis with very good results in the treatment of uremia, and it is believed that not only are the poisons washed out of the system by this method, but, in addition, that the dilution of the poisons prevents them from acting so severely. In septicemia, diabetic coma, and similar states this method of treatment should be employed and the results carefully recorded. When general dropsy is present it is manifestly useless. Hypodermoclysis has also been used with great advantage in the treatment of severe burns to overcome shock and toxemia. In cases of surgical shock warm saline fluid used by hypodermoclysis is often of great service."—(Hare's *Therapeutics.*)

"Hypodermoclysis "may be given in the thigh, the buttocks, back, chest, or, in women, in the submammary region. The quantity of fluid introduced at one time varies from ½ pint to 1 quart. It requires an apparatus consisting of a hard-rubber funnel, 4½ feet of rubber tubing, and a hollow needle, all of which should be sterilized before being used. The solutions should be filtered and sterilized, and should be administered at a temperature of 100° F., under aseptic precautions. Normal salt solution may be used, and is made by adding sodium chloride, one dram, to water, one pint."—(*Pocket Cyclopedia.*)

12. *Treatment of acute articular rheumatism:*—"In all cases the patient should be placed at absolute rest in bed. He should wear woolen garments, and blankets (no sheets) should constitute the bed clothing, care being taken to protect the inflamed joint from excessive weight of the coverings. The diet should consist of easily-digested substances, preferably milk. The free use of water, particularly the alkaline mineral waters, should be encouraged. In strong and vigorous patients the administration of salicylic acid or the salicylates in large and frequently repeated doses is of great benefit. Sodium salicylate, ammonium salicylate, strontium salicylate, salicin, aspirin, salol, salophen, or oil of wintergreen may be used and pushed to the point of tolerance. In all cases, special internal treatment should be preceded by a course of calomel followed by a saline laxative. . . . Usually this treatment affords rather prompt relief but if after three or four days' trial there is no benefit derived from it, alkaline treatment should be substituted. This consists in the administration of an ounce and a half of one of the alkaline carbonates, either alone or combined with a vegetable acid, every twenty-four hours until the urine becomes neutral or alkaline when the quantity should be reduced to an amount just sufficient to maintain alkalinity."—(Hughes' *Practice of Medicine.*)

13. *Five drugs used hypodermically:*—Apomorphine hydrochloride, 1/10 grain, as an emetic; Morphine sulphate, ½ grain, to relieve pain; Strychnine sulphate, 1/32 grain, as a cardiac and respiratory stimulant; Hyoscine hydrobromide, 1/128 grain, as a hypnotic; Cocaine hydrochloride, 2 per cent. solution, as an anesthetic (local).

14. *Thyroid extract* is given in doses of 4 grains, in cases of myxedema, cretinism, hyperplastic follicular goitre, and arteriosclerosis.

15. *Adrenalin* is generally given in dose of 5 to 10 drops of a solution 1: 1,000. It is a cardiac stimulant, it slows the pulse rate, is a vasoconstrictor, raises the blood pressure, and diminishes peristalsis. Its main use is to constrict the peripheral blood vessels, and so arrest hemorrhage.

(*To be continued.*)

Therapeutic Hints.

Recurring Cholecystitis.—Einhorn holds that the treatment of recurring cholecystitis, with or without stones during the latent stage, has two objects: (1) to reduce stagnation of bile, and (2) to combat infection. The former is accomplished by drinking large quantities of water. Cures at Carlsbad, Kissingen, Vichy, Saratoga, or French Lick Springs combine the advantages of water, mild aperients, and restful surroundings, which are of benefit for establishing a healthy liver function. Frequent and small meals of wholesome food (mixed diet, with plenty of green vegetables and fruits) are likewise of much assistance in increasing the flow of bile. The infection is best combatted by urotropine, salicylic acid, salol, aspirin, and again by flushing the gastrointestinal tract with great quantities of water. Einhorn has found that glycerin given in teaspoonful doses, three times daily, exerts an antiputrefactive action on the bile. Patients who have been given this medicine furnish a bile that can be kept from one to two days without decomposition, while otherwise, the duodenal secretion after being exposed for a few hours in the air begins to smell badly and in about six hours develops a putrid odor. He prescribes, in this connection, the following:

Sodii bicarbon	℥ i i
Glycer. pur	℥ i i
Aq. dest	℥ v

M. Sig.: ℥ss. three times a day, one half hour before meals.

Antiseptic and astringent solutions can likewise be instilled directly into the duodenum, in order to exert a beneficial influence in this locally, which also has an effect on the biliary passages. Ichthyol (one half to one per cent.) or argyrol in the same strength (blood temperature) can be thrown into the beginning of the duodenum in amounts of from ten to twenty c.c. daily or every other day while the patient is in a fasting condition. When biliary calculi are known to exist and give rise to difficulties through their migrations, olive oil administered in four to five ounce doses once or twice daily, has been believed to have a good influence on the passage of the stones. This can refer only to small calculi; but even then, the effect of the oil is problematical. Its action, however, is never harmful, and for that reason it can always be employed in appropriate cases.—*New York Medical Journal.*

NOTES ON MOTILITY.

BY E. H. P. WARD, M.D.,

WHITE PLAINS, N. Y.

THERE are a few additional points of interest that have occurred to me since writing my paper on "Motility in the Animal Organism" (MEDICAL RECORD, Jan. 10, 1920), or which I did not have space to include in that paper, or which are more or less obvious inferences from the hypothesis there advanced to account for the phenomena of spontaneous or automatic movement in animals.

I might note here that this hypothesis may probably explain the phenomena of motility in *plants* as well as in animals, and thus reduce all motile phenomena, which constitute the most characteristic obvious attribute of life, to a common basis as being a direct result of combustion with liberation of CO_2 gas. In plants, the protoplasm is confined in cells whose walls are more or less rigid and impermeable and the CO_2 produced in catabolism may have to travel some distance to seek an outlet and may generate considerable pressure before finding one. And instead of changing the shape of the cell or a modified portion of it, it produces currents in the protoplasmic contents of the rigid cellulose walls, similar fundamentally to the ameboid movements of animal cells, but resulting not in locomotion of the organism but in circulation within it. Thus it sets up the well-known streaming movements in the protoplasm of plant cells and probably plays the principal part in causing the sap to rise in trees—a phenomenon which has long puzzled botanists. In the spring, when the ground is saturated with moisture, water is drawn into the roots by osmosis; then, as the ground gets warmed up, combustion of carbohydrate substances starts up in the roots and other parts of the tree and CO_2 gas is liberated. Now this gas cannot escape until it has passed to the top of the tree, where it is disposed of by the leaves, being either built up again with water to form starch or expired into the surrounding atmosphere. But the system of tubes and cellular spaces through which this gas must pass to reach the leaves is not empty but filled more or less with sap; and the gas in rising through the sap carries the sap with it or forces it ahead of it much like the gas in a syphon of soda-water; only, of course, the flow is not so violent in the tree as in the syphon, because the pressure is slow and steady, and especially because the sap must flow through a system of very fine tubes and spaces. Thus the effect is that of a pump, the osmotic action being comparable to that of a multitude of check-valves and the motive power being the pressure generated by the liberation of gas in the liquid to be pumped.

But of course our principal interest here is in the animal organism, and there are a number of theoretical considerations which follow from this hypothesis and which may throw light upon problems of practical importance to the physician. In the first place there are certain inferences to be drawn as to the *structure and functions of the cell*—fundamentally important problems upon which the old theory of motility (that protoplasm is essentially "contractile") throws no light, but which, on the contrary, it makes more mysterious and insoluble. This conception of "contractility" arose, no doubt, from an incomplete understanding of muscular action, which was the first form of animal movement to be studied, and was later applied by analogy to the other forms of motion—ameboid, flagellate, ciliate, etc.—where it is even more baseless, for in these other types of motion no contraction is even apparent. Nobody has been able to suggest a reasonable interpretation of the structure of protoplasm on the basis of the conception that it is essentially "contractile," nor has this term any real meaning as an essential property of protoplasm, nor can contraction of protoplasm be conceived of as a direct result of the combustion that is supposed to produce it. One theory advanced was that protoplasm consisted of, or contained, a contractile network, based on the supposition that the microscopic structure of protoplasm is *reticular*. But the characteristically motile portion of the cell—the outer layer or ectoplasm—is not reticular but alveolar in structure, resembling a mass of fine bubbles, each bubble being ½ to 1 μ in diameter. Thus the theory of contractility is based upon a false analogy drawn from an incomplete understanding of muscular action and has no real foundation in fact or in reason. Whereas the hypothesis that motility results from an expansion of the viscid protoplasm substance by CO_2 gas resulting from the combustion of catabolism is inherently reasonable, agrees with the known facts and seems to furnish a satisfactory interpretation of them.

Let us now cosider the typical animal cell in the light of this hypothesis. It consists of the nucleus, the endoplasm and the ectoplasm. The ectoplasm or outer layer of protoplasm is tough and viscid, transparent, and alveolar in structure. It is probably the principal, perhaps the only, seat of combustion in the cell; for here the combustible protoplasm, built up in the endoplasm under the influence of the nucleus, comes in contact with the oxygen of the outer world. This combustion uses up carbohydrate substances principally and produces among other things urea, water, and CO_2 gas. The urea is dissolved in

the water and both pass to the outer world, sometimes being collected first from all parts of the ectoplasm into a single drop and excreted by the contractile vacuole. The CO_2 gas, however, formed throughout the viscid substance of the ectoplasm and especially abundant at the surface, collects in minute bubbles and both causes the tough viscid ectoplasm to swell or expand and also gives it its alveolar or honeycombed structure and its transparency, just as baking-powder under the influence of heat forms minute bubbles of gas in viscid dough and causes it to swell up and take on a honeycombed structure. The alveoli around the outside of the ectoplasm are often arranged in lines radiating from the center of the cell, representing probably the paths of escape of the gas bubbles which gradually leak out everywhere through the substance of the ectoplasm, which is not viscid enough to retain them indefinitely, although it may retain the watery products of catabolism until, under the laws that govern liquids that do not mix, they collect into a drop large enough to overcome the viscidity and surface tension of the surrounding ectoplasm. Thus we can account for the *motility*, the *transparency*, and the *alveolar structure* of the ectoplasm as resulting from its toughness and viscidity and the combustion which is assumed to take place within it.

But there is another factor involved here whose importance must be fundamental in cell metabolism —the factor of *heat*. Of course, heat must be liberated by the combustion in the ectoplasm; and while no doubt much of it is lost to the external world, a large part of it must pass inward to the endoplasm and the nucleus. If we compare the cell to a candle flame, the bright outer portion of the flame corresponds to the ectoplasm of the cell. Here the combustible material is in a form to be consumed readily, and here it comes in contact with the oxygen necessary to consume it. Most of the heat liberated passes to the surrounding air, but much of it passes to the interior of the flame, where it volatilizes the oil or paraffin that is drawn from the wick and thus prepares it for rapid combustion. Similarly, the heat from the burning ectoplasm that passes inwardly to the endoplasm and the nucleus must raise these internal parts to a relatively high temperature and no doubt furnishes the nucleus with a source of energy which alone enables it to digest food substances and build the products up again in *anabolism*. And this intracellular heat is no doubt finally disposed of in anabolism by being stored up in endothermic compounds of protoplasm built up under the influence of the nucleus in the endoplasm of the cell. And when they pass in their turn to replace ectoplasmic substance and to be consumed in catabolism, this endothermic heat is liberated once more in the ectoplasm and part of it passes again to the interior of the cell to repeat the process. Thus in part the cell is a mechanism for using the same energy, in the form of heat, over and over again; and this perhaps explains one of the fundamental mysteries of life, the fact that the cell seems to have some mysterious source of energy which led the older biologists to consider that there might be a special vital force. But of course the loss of heat to the exterior must be replaced by food, which no doubt furnishes considerable of its heat to the interior of the cell when it is partly split up in the process of digestion and the balance when it is consumed in catabolism. Of course, the animal cell cannot utilize the energy of the sun as the plant cell can in building up carbohydrates, etc., but yet heat from the exterior of the cell may supplement this intracellular heat as a factor in anabolism. This intracellular heat may perhaps be an important factor in disease, and I shall refer to it subsequently. It is no doubt a fundamental factor in health, and explains in part at least the physiological axiom that no organ can long maintain its vitality without exercise. Without exercise, or catabolism, the nucleus and endoplasm of the cell are not raised to a temperature sufficiently high to make possible the building up of new protoplasm in anabolism. Hence the cell or organ not only cannot grow but gradually wastes away from what little catabolism may persist. Now, in conditions of lowered vitality due to disease or senescence, the cells cannot produce sufficient intracellular heat through their own catabolism to enable the nuclei to function properly and build up new protoplasm. This might be a result of diseases of metabolism or a cause of such diseases, perhaps the products of incomplete anabolism being toxic to the organism. Now, in these diseases, the application of external heat to the organism—by hot baths, sun baths, a warm climate, etc.—may supplement the heat of catabolism and enable the nuclei to function normally and build up normal anabolic products. Thus in senility the high frequency electrical current, whose only known effect is a raising of the internal temperature of the organs, seems to improve vitality and rejuvenate the organism.

On the other hand, *overactivity* of a cell or of an organ may raise the internal temperature of the cell or cells to an excessive degree and damage the nucleus temporarily or permanently. This might be expected to occur especially in fevers, and the granular and fatty degenerations more or less characteristic of all the organs in fever may be a result of it. Toxins also may play a part in these cellular degenerations, both in fever and in other cases; but high temperature alone, as shown by experiments on animals, will produce these degenerations. Perhaps it is in this way that the heart muscle becomes diseased through overwork, resulting in permanent weakening and fatty degeneration; I shall show later why the heart muscle is especially susceptible to injury from excessive intracellular heat. Possibly *obesity* is a permanent fatty degeneration of more or less all the cells of the body resulting from injury to the nuclei so that they can no longer build up fatty substances into protoplasm; this injury might result from toxins or from excessive intracellular heat, and seems to occur temporarily at least after certain infectious diseases, especially typhoid fever.

To continue with the consideration of the structure and functions of the cell, the *endoplasm*, or inner layer of protoplasm, is more fluid than the ectoplasm and is less transparent, due to the fact that its structure is more or less *granular* instead of being filled with gas bubbles. Here the food substances, captured and ingested from without by the ectoplasm, are broken up into simpler substances—the proteins perhaps into peptones or amino-acids—and resynthesized into the complex protoplasm characteristic of the particular cell; and the granules are

supposed to represent stages in this process or reserve substances stored up, or perhaps by-products to be excreted. Thus the endoplasm is the kitchen of the cell, the ectoplasm bringing in the food and furnishing the heat to prepare it, and the nucleus being the cook working perhaps with enzymes as utensils. Now there is more or less generally present in the endoplasm a most mysterious body—the centrosome—about whose nature we know very little. Usually inactive and inconspicuous, near the nucleus, it plays a conspicuous part in cell division, and also seems to be concerned in the flagellate movements of the spermatozoön and with ameboid movement in white blood cells. I have nothing much to suggest with regard to it, unless it be that it represents a focus of intense combustion. Its relation to ameboid movement and the fact that the cell wall near it often bulges outward in cell division would indicate pressure exerted by its proximity such as might be given off by CO_2 gas resulting from rapid combustion. The centrosome might act in some such way on the flagellum of the spermatozoön. A rather fanciful explanation of its nature, but perhaps no less reasonable than some that have been suggested, would be the following: one suggestion as to why the cell divides is that when it has grown to a certain size it can no longer be nourished, etc., properly, since its bulk increases as the cube of its radius, while its surface increases only as the square of its radius. Now, the larger the cell grows, the more intense must be the heat that accumulates in the interior from the combustion in the ectoplasm; and yet there must be a definite limit to the temperature at which the nucleus can function or even survive. Now, the centrosome might be a sort of safety-valve set to go off at a certain temperature—a sort of slow-burning fuse or bomb made up of combustible material of high potential energy; and when the intracellular temperature reaches a point at which the integrity of the nucleus is endangered, the centrosome may, by bursting into two parts and one part passing to either pole of the cell, each one starting to burn and liberate gases, gradually blow the halves of the cell apart by the pressure of the liberated gases, half the chromosomes being blown one way and half the other way. Personally, I am not much impressed by this explanation, and yet it might have a germ of truth in it. One of the most frequent and characteristic manifestations of cell irritation or derangement is a rapid multiplication of cells or perhaps only the formation of mitotic figures in them. Now, if irritation can produce overactivity of a cell and this overactivity can cause excessive intracellular heat; and if the centrosome is a cell-dividing mechanism set in action by dangerously high intracellular temperatures, we might expect the centrosome to respond to a temperature generated by overactivity of the cell as well as by overgrowth of the cell, and thus we might explain why cells divide not only as a result of growth, but also as a result of irritation.

The nucleus of the cell is infinitely more complicated than the ectoplasm or the endoplasm, and quite beyond our comprehension in the present state of our knowledge. Its essential part—the linin reticulum, with the nuclear chromatin embedded in it or grouped irregularly at its nodal points—is *reticular* in structure, which allows the greatest possible amount of its surface to be exposed to the surrounding clear, fluid caryolymph which probably serves as a medium of communication between the chromatin and the endoplasm, through the nuclear membrane. The nucleus is the great mystery of the cell, and while it represents, no doubt, a problem in chemistry and physics, it is a quite insoluble one in the light of our present knowledge. The essential constituents of the chromatin seem to be nucleoproteins—the most complex chemical substances known—and we cannot conceive of their chemical complexity, to say nothing of their stereochemical structure; and much less can we explain their functions in terms of their structure. But the nucleus seems to be the essential active constituent of the cell, the endoplasm and the ectoplasm representing a sort of working capital stored up by the activity of the nucleus. The nucleus can, by means of enzymes, whose nature and mode of action are unknown, impart to protoplasmic and other suitable foreign substances its own characteristics and build them up by intussusception into its own substance; or it can impart to such foreign substances such a chemical composition and structure as will enable them, grouped about the outside of the cell in the form of ectoplasm, to move the cell away from a harmful influence or toward a beneficial one; and an instance of the latter is when the cell is moved toward food substances and surrounds them, as in the amœba; then these new food substances are taken into the endoplasm and trained to take the place of the ectoplasm which has been consumed in their capture. The process seems simple enough, but the mechanism by which it is accomplished is inconceivably complex. And then the nucleus has the property of dividing in such a way as to form two similar nuclei. Even if we could analyze completely the activities of the cell, as we may some day be able to do, we shall probably never be able to fathom the infinite ocean of matter and energy from which Life, in common with inanimate nature, takes its rise; or to foretell the complexity of structure and function of which it may be capable in the future. It is like a comet that flashes across our field of vision; we may study its form and structure as it passes, but whence it comes and whither it goes we know not.

Thus I have considered some of the principal characteristics of the typical cell in the light of my hypothesis of motility, but these characteristics are, of course, modified in different types of cell. We are interested here chiefly in the muscle cell, and I shall briefly refer to a few of the modifications. The ectoplasm is especially, if not exclusively, concerned in motility, and some of the protozoa that have lost their ectoplasm have lost their power of movement along with it—*eg.* the gregarines and the macrogametes. Flagella and cilia arise from the ectoplasm, also the trichocysts found in certain Infusoria. Muscle fibrils also appear in the ectoplasm, beneath the cuticle, in ciliates, etc. In the pseudopod, the toughness and viscidity and the combustibility of the ectoplasm are present together, while in the flagellum, cilium, and muscle fibril these characteristics of the ectoplasm seem to have parted company, the toughness and viscidity being concentrated in the fibrous outer envelope or mem-

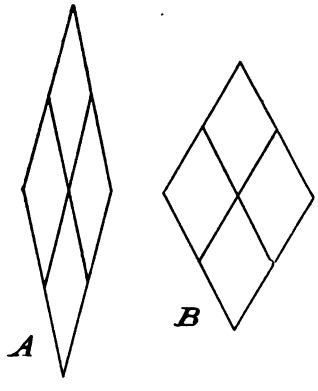
brane of the flagellum, cilium, and fibril; the combustibility being concentrated in the enclosed protoplasm. In the smooth muscle cell, the fibrils occupy the outer portion of the cell and no doubt represent the ectoplasm, while the nucleus in the center is surrounded by the sarcoplasm, which probably represents the endoplasm. Similarly with the cells of cardiac muscle. But in the voluntary or striped muscle fiber, the nuclei have left the center of the cell and come to the outside, where they lie just under the sarcolemma sheath. Now, this change in the position of the nucleus is probably of great significance. Smooth muscle fibers contract slowly and probably do not generate an extreme degree of heat in the interior of the cell; but voluntary muscles, with their extremely rapid and prolonged tetanic contractions, must generate a relatively enormous amount of heat; especially as the muscles are not spread out in thin sheets, but gathered into dense masses. Probably the nuclei of the striped muscle fiber have moved to the outside of the cell to escape the excessive heat in the interior of the fiber. If during severe muscular exertion the temperature of the surface of the body can be kept below 100° Fahr. only by the aid of every cooling device at the command of the organism, consider what the temperature must be in the heart of the furnace where all this heat is generated—the interior of the voluntary muscle fiber; it must be dangerously near the limit for heat rigor and far more than the delicately organized nucleus could stand. But at the surface of the fiber the nuclei are cooled by the blood and lymph. Thus voluntary muscles do not as a rule suffer from overstrain. But the heart muscle, while its structure in this respect is primitive like that of smooth muscle, is yet called on to perform much heavier and more constant work than any smooth muscle. The heart probably is an organ imperfectly adopted to serve its function, so far as the arrangement of the nuclei of its muscle fibers is concerned, although a marvelously efficient mechanism from a mechanical standpoint. Overactivity, especially of the ventricular muscle, which is so much denser a mass than the auricular muscle, probably overheats the nuclei and permanently impairs the nutrition of the cells, giving rise to the characteristic granular and fatty degenerations and in extreme cases to disappearance of the cells and their replacement by fibrous tissue. The voluntary muscles, on the other hand, furnish a striking illustration of the axiom that an organ cannot retain its vitality without exercise, as shown in the degenerative changes that follow lesions of the nerves that supply them. They also furnish strong corroboration of this entire proposition of *intracellular heat*, for it has been shown experimentally that during severe muscular exertion the muscles alone may generate more heat than the entire amount given out by the body. What becomes of the balance? It must be absorbed by the interior of the cells and stored up in endothermic protoplasmic compounds in the process of anabolism.

This whole question of nutrition in the higher forms, such as man, is very complicated. The amœba takes and digests and assimilates food when it finds it; but in the human organism the cells of the body are bathed continuously in liquid food, and how are they controlled in the use of this food? Do they keep continuously gorged to the limit, or do they feed at intervals; and if the latter, what controls the intervals? No doubt this intracellular heat produced by catabolism during exercise is one of the principal factors, but there may be other factors. Perhaps the trophic nerves stimulate the nuclei of the cells to produce enzymes which bring about anabolism in the presence of this heat and the ever-present food substances. Perhaps *inhibitory* nerves are really trophic in their action and by thus stimulating anabolism use up this intracellular heat faster perhaps than it is formed by catabolism, and thus by reducing the cell temperature, slow down or inhibit activity. If this were the case we might understand why the highest brain centers are the most delicate and vulnerable; there are no higher centers to inhibit them—*i.e.* to promote their nutrition by trophic innervation. In the nerve cells the ectoplasm is probably represented by the cell processes—the axis-cylinders and dendrites—and the ectoplasmic combustion, instead of producing motion, serves as a means of communication by transmitting impulses in the form perhaps of explosive waves passing along these processes. Only an insignificant quantity of fuel is consumed in these explosions, but it is of such high potential energy that it must be difficult for the cell to replace, especially in the axis-cylinder processes which may reach a length of two or three feet. What may be the nature of the nerve impulse—whether impulses differ qualitatively or quantitatively or in the intervals between them (like the impulses on a telegraph wire)—it would be difficult to say; also, whether their inhibitory, trophic, motor, or secretory influences on the organs of the body are due to impulses of different nature or to these impulses affecting different parts of the cells. Similarly, in the central nervous system: the reaction of a cell in the gray matter to an impulse reaching it along an axis-cylinder process might vary with the quality or strength of the impulse or with the dendritic process through which the impulse is communicated to the cell. And the nature of the mechanism by which the memory of previous impulses is stored up, constituting instinct or experience; and by which new variations and combinations can be originated in reaction—this mechanism is quite beyond our comprehension. But it may be that during the process of thought and contemplation, which may extend over a period of years without resulting in definite conclusions, new connections may be made between neighboring cells by means of a new formation of the finer processes of the axis-cylinders and dendrites; and when the new connections are complete, the conclusion suddenly dawns upon us and seems obvious as, indeed, it is when we can take a short cut to reach it. Memory may have its basis in paths of conduction blazed in the ectoplasm of the nerve cell by previous impulses, or it may have its seat in the nucleus; the reactions of the cell to various stimuli depending upon the chemical complexity and structure of its ectoplasm whose substance is ever changing, being consumed in activity and replaced by the action of the nucleus, which stamps upon it its own characters received by heredity and modified by experience.

The action on muscle of various drugs is of interest in connection with this hypothesis of motil-

ity, but the explanation is not always obvious. But *curara* probably acts on the "myoneural junction" "which serves to transfer the nerve impulse from the end-plate to the actual contractile substance of the muscle" (Cushny), and this myoneural junction is probably the sarcoplasm. Veratrine has the remarkable power of increasing and prolonging the contractions of voluntary muscles, and may act by impeding the escape of CO_2 gas through the fibrillar membranes.

Then there is the mechanical problem involved in my hypothesis; and I have the word of an eminent authority on mechanics for it that this problem is of great difficulty as well as of great interest. I shall merely try to state it. The human organism regarded as an internal-combustion engine, seems to be more efficient than any steam or gas engine, as much as 35 per cent of the energy consumed as fuel being transformed into effective work; and this, I believe, results from the mechanical efficiency of the muscular mechanism. In the cylinder of a steam or gas engine only a small part of the surface exposed to the pressure generated (viz., the piston) is free to respond to this pressure and transform it into working power; most of the pressure is wasted upon the immovable cylinder walls and the cylinder



A, Extended; *B*, Contracted.

head. But in the muscle fiber or the primitive fibrils within it, all the expansive force of the CO_2 gas liberated within it during a contraction is utilized because the containing walls are free to expand in every direction transversely to the long axis of the fiber and no energy is wasted at the ends of the fiber, trying to stretch it longitudinally, because the ends taper down to a point. Now we might expect that when a number of these expanding fibers are placed side by side in a muscle, they would, by expanding against one another, more or less interfere and produce a less powerful traction at the ends of the muscle. This may happen in the ventricular muscle of the heart, but is probably of no importance because, as I have suggested in my former paper, the shortening of the fibers in contraction of the ventricular muscle is probably of less importance than their transverse expansion. But in bands of smooth muscle and in the voluntary muscles, this interference is guarded against by (1) the shape of the fibers, tapering at the ends, and (2) the alternate arrangement of the fibers overlapping one another; and the effect of this arrangement is illustrated by the following diagrams, representing longitudinal sections of a muscle:

Thus a longitudinal section of the muscle would resemble a lattice-work that is closed and extended when at rest and opened and shortened in action; and it does not seem that the transversely expanding muscle fibers would interfere with one another, if indeed they do not even assist one another. The lines marking off the individual fibers in the diagram would correspond to the inextensible white fibers passing more or less continuously from one end of the muscle to the other through the walls of the sarcolemma sheaths, and transmitting the power generated by the contraction to the tendons at either end, which are indeed made up of these fibers. And from the diagram it is obvious how these inextensible fibers must be shortened by the transverse expansion.

Thus it would seem that all the energy of expansion is utilized in the muscle, but it is not all transformed into *motion* at the ends of the muscle, although it is probably all applied there in the form of *power* to do work; or may perhaps be even multiplied by a principle analogous to leverage, according to which motion is sacrificed to power. Thus it would compensate for the poor leverage resulting from the manner in which the tendons are attached to the bones—so near the fulcrum—where power is sacrificed to motion. It seems to be a most extraordinary and wonderfully efficient mechanism, and so far as I am aware is unique in mechanics. So far as I know, the only approach to it is the case of a rope shortening when wet. This is supposed to exert a relatively enormous pull, although through only a short distance, and resembles the muscle action in that the shortening results from a transverse expansion of fibers longitudinally inextensible; only in the rope the transverse expansion results from water drawn into the interstices of the strands by physical or chemical attraction, whereas in the muscle it is due to the expansion of gas liberated within the hollow strands. If we could measure the amount of CO_2 gas liberated in a muscle during contraction and ascertain the temperature at which it expands, we could calculate the expansive force generated by it. Then if we could solve the mechanical problem involved here and find out what proportion of the expansive force acting upon such a mechanism is transformed into work at the ends, and compare the result with the work actually done by the muscle in contracting, we might be able to test this theory experimentally. The work done by a contracting muscle may possibly vary according to whether both ends are free to move, or one end is fixed, as in most skeletal muscles, and the other end alone free to draw up in contraction.

The mechanism of the ventricular muscle of the heart is even more remarkable than that of other muscles. Imagine a pump in which, instead of the piston alone compressing the water, the entire wall of the chamber shrinks and at the same time swells into the cavity, obliterating it; both shrinkage and swelling being due to a single mechanical device operated by a single expansive force. It is interesting also to consider the wing muscles of insects. The wasp is said to ply its wings at the rate of 110 beats per second, and the common house fly at 330 beats per second (the high-pitched notes being produced by secondary vibrations of the margins at a much higher rate). Now, it is remarkable that

muscles can contract so rapidly; it must be just a series of instantaneous explosions, and the gases liberated must escape from the fibrils and fibers almost instantaneously. And it is significant that these gases do not have to be absorbed and carried away by circulating blood but are pumped out to the external air through a system of intake—and—exhaust tubes which ramify directly to the muscles. The interchange of gases must be on a relatively enormous scale and probably no system of circulating blood could cope with it. This whole mechanism seems to suggest the probability that the CO_2 produced here is something more than a mere incidental waste product of muscular action.

It seems not impossible, however, that there may be other factors in the expansion of the muscle fiber (and perhaps also in other motile mechanisms) in addition to the CO_2 gas liberated as a result of carbohydrate combustion; and I have had this possibility in mind all along, although I have spoken of the CO_2 alone as an expansive agent partly for the sake of simplicity and partly because it is the only one of which we have any definite knowledge. This perhaps is a good opportunity to consider more closely the nature of the changes that occur in the muscle fiber during a contraction. In an explosion there are two factors which operate to produce the expansive energy which results; one of these factors is the sudden transformation of molecules from a solid or liquid to a gaseous state with resulting expansion; the other factor is the heat which is liberated by the chemical changes accompanying this transformation, and this heat may be the result of oxidation or it may be *endothermic—i.e.* stored up in the molecules of the explosive substance and liberated by the breaking up of these molecules; and in either case this heat increases the expansion of the gaseous molecules formed by the explosion or already present. Now, these two factors may operate together or more or less separately according to the nature of the explosive substance. Thus there are a number of substances—the acetylides and some nitrogen compounds, as nitrogen chloride—which decompose with extreme violence, and yet but little heat is produced. On the other hand, in the internal combustion engine, with certain kinds of fuel, there are actually fewer gaseous molecules present after the explosion than before it, but such a great amount of heat is liberated by the oxidation that these molecules of gas exert a tremendous expansive force; and in internal combustion engines in general, the heat generated by the combustion of the fuel in the cylinder is practically the only factor of importance in producing the energy of expansion, the formation of new gaseous molecules even when it does occur being a negligible factor in comparison. These cases represent the two extremes, the one where the expansive force is due almost entirely to the liberation of new gaseous molecules, the other where it is due to the heat liberated expanding an unchanged or even a diminished volume of gases. In most explosions, however, both these factors operate together although one may be more important than the other. Now in the living organism, if the power of movement is the result of carbohydrate combustion of a more or less explosive nature, which liberates CO_2 gas among other products, it is obvious that heat can play but a secondary and strictly limited part as a factor in the resulting expansion, because the temperature cannot consistently with life be raised above the coagulation point of proteins or of heat rigor in muscle, which is about 50° C. (122° F.). Hence the pressure of expansion must be due principally to the formation of new gaseous molecules such as CO_2, although the moderate amount of heat liberated no doubt materially increases their expansive energy and diminishes their solubility in the liquid medium in which they are liberated. Thus the automobile cylinder, where the heat is the only important factor, constitutes but an imperfect analogy to the muscle fiber. Now, apart from theoretical considerations, we know practically that when carbohydrates are decomposed the CO_2 gas liberated exerts considerable expansive force; this is a matter of every day experience in the fermentation of sugars, the CO_2 generated at a moderate temperature exerting a tremendous pressure even though only about half the carbon available in the sugar is oxidized to CO_2, the remainder being contained in the alcohols and other products of fermentation. Therefore it is not unreasonable to suppose that when in the muscle fiber all the carbon in the carbohydrate molecules is suddenly combined with oxygen and liberated as CO_2, a very considerable expansive force must result. But, as I stated above, it is not impossible that there may be other factors, in addition to the CO_2, which act in producing the expansion of the muscle fiber. It was by no means a simple problem for the early engineers to find out exactly what occurred in the cylinder of the internal combustion engine, where conditions are comparatively simple. But when we try to work out the thermodynamics of the muscle fiber, we are handicapped from the start by the fact that we have scarcely any conception whatever of the chemical aspects of the problem. We can hardly conceive even of the structure of the proteid molecule; and when we try to picture one or more carbohydrate molecules combined in some way with the proteid molecule, and then suddenly exploding during a muscular contraction, and then try to figure out just what happens chemically and physically, it is obvious that we can do little more than speculate. We know that a lot of carbohydrate and of oxygen is used up in muscular work, and a lot of CO_2 produced. Lactic acid is produced, presumably from imperfect combustion of the carbohydrate; and urea and other nitrogenous compounds are formed, presumably from proteid decomposition, which is generally supposed to result from the explosion of the carbohydrate group while it is incorporated in the proteid molecule. But the fact is that we know very little about what actually takes place. An important point to bear in mind is that we are dealing, not with a reaction or series of reactions between more or less fixed and inert chemical substances in a test-tube or in the cylinder of an internal combustion engine, but with a living cell; only living muscle fibers contract. And if we do not understand the precise chemical structure of the component parts of the dead cell, how can we hope to conceive of all the actions and reactions and interactions of these parts in the living cell? For all we know, it may be that an extremely complicated series of chemical changes occurs in the proteid molecules of motile protoplasm; in their liv-

ing liable state they may be highly explosive, like the diazo compounds exploding not as a result of oxidation but by virtue of the peculiar state of union of their nitrogen; their explosions perhaps being set off by the carbohydrate combustion or coincident with it. And the resulting products, including gases like nitrogen and hydrogen, or their compounds, may exert a momentary expansive pressure of great force; and then, being not in a test-tube or automobile cylinder but in a living cell, these products may under the influence of enzymes, etc., and of the intracellular heat to which I have referred to above, be resynthesized in large part into proteid substances, only a small part being lost in the form of urea and other nitrogenous compounds. There seems no reason why the nitrogen and hydrogen that go to form urea might not exist momentarily in a gaseous form before combining. Just as a hydraulic ram utilizes the energy of falling water to raise part of the water again, just so the living cell may use part of the energy of decomposing proteid and carbohydrate substances to synthesize some of the products into new proteid substances. Some of the energy is of course lost and must be replaced by food, but much of it may be used over and over again. This might be another reason why the human organism is so efficient as an internal combustion engine. Whether or not some such factors are concerned in muscular action we do not know; for whether it seems probable or not, we can hardly say it is impossible. While we know pretty well what goes into the cell and what comes out of it, the changes that take place within the cell during life are unknown to us. Therefore, even if the expansive force of the CO_2 liberated in muscular action should prove to be insufficient of itself to account for the work done by the contracting muscles, it would not necessarily disprove this hypothesis of motility. And it was because I believed that in the present incomplete state of our knowledge it is not now possible to prove or disprove the validity of this hypothesis that I ventured to suggest it to the medical profession and to physiologists and biologists without attempting to supply new experimental data in support of it, believing that its inherent reasonableness and its agreement with the principal known facts and the readiness with which it lends itself to the interpretation of these facts entitle it to the serious consideration of scientists as a working hypothesis to be held until disproved or replaced wholly or in part by a better one.

Finally, there are certain general considerations on the nature of stimuli. In my former paper, I suggested that in the amœba and in flagellates stimuli may act directly on the motile organs causing the cell to approach or retreat from the source of stimulation without any central control of orientation from within the cell; without anything that can be considered analogous to a conscious purpose on the part of the organism. Now I believe the same thing may apply to the ciliates, although here the mechanism is more complicated on account of the great number of cilia. The movements are well studied in *Paramecium*, where Jennings has found that the long axis of the cell does not point directly toward the source of stimulation as the organism is advancing, but is inclined at an angle; and the entire organism traces a spiral whose axis is described by the posterior end of the cell. This is what might be expected if the stimulus acts directly on the individual cilia, for if it strikes the organism from one side the cilia on that side would be thrown into action more strongly than those on the opposite side of the cell and would thus keep the organism inclined at an angle; while the stimulus upon the cilia on the upper and lower surfaces of the cell would propel the organism in the desired direction. But for some reason the stimulus does not act with equal force on the cilia on the upper and lower surfaces and thus the cell rotates about its long axis as it advances, and this results in successive sides of the cilia being exposed to the stimulus, which is no doubt an advantage. The mechanism is rather complicated but it seems possible to explain the reactions of these organisms on the same principle as in the amœba. The essential point is that in the unicellular forms the stimuli probably act directly on the motile ectoplasm by either increasing its combustion (positive stimuli) or diminishing it (negative stimuli). And the degree to which different parts of the motile organs are affected determines the direction in which the organism moves. Just why any particular stimulus should increase or decrease combustion in the ectoplasm is a mystery wrapped up in its chemical composition and structure, which is modified by the chemical or physical action of the stimulus. So long as life remains in the organism, a certain amount of combustion no doubt constantly takes place. Any influence that increases the rapidity of this combustion up to a certain limit can act as a positive stimulus and even from a distance by chemical or physical action can by increasing combustion on the side of the organism nearest to it draw the entire organism toward it; and conversely with negative stimuli. But the reaction of the organism is always the resultant of the stimulating forces that may at any given moment act upon it from various directions; and a force that may act as a positive stimulus when opposed by a set of forces that exert a less beneficial influence upon katabolism, may act as a negative stimulus when in the presence of other forces that exert a more beneficial influence. Thus *positive* and *negative* are relative terms as applied to stimuli, and there is no stimulus absolutely negative except death and perhaps none whatever that is absolutely positive. Furthermore, a negative stimulus can probably never produce a positive reaction but merely increase by contrast the effect of a more positive stimulus already present. When danger looms up from one quarter, the prospect of safety in the opposite direction becomes a strong and compelling stimulus; whereas if a still greater danger threatens in this direction, the former danger may seem safe by comparison and what was formerly a negative may become a positive stimulus by contrast. When danger is equally great from all sides, and no path of escape presents itself as a positive stimulus, the organism, whether the amœba or man, stands rooted to the spot in a condition almost of suspended animation ready for the only absolutely negative stimulus, death. The same principles hold throughout the animal kingdom, from the amœba to man. A negative stimulus, pain, grief, seem to

depress catabolism, to cause shrinkage of the organism with lowering of temperature, due no doubt to diminished combustion and reduced formation of expansive CO_2 gas; while a positive stimulus, pleasure, joy, seem to stimulate catabolism and to cause expansion of the organism and an elevation of temperature. Thus we see perhaps why pain and grief are necessary lest the fires of life be burnt out too rapidly. Perhaps in nervous disorders such unpleasant drugs as valerian and asafetida may act by checking too rapid combustion of the tissues. The relative effects of positive and negative stimuli on man are well illustrated by the old fable of the Traveler, the Storm, and the Sun. The whole life of man is a quest for the absolutely positive stimulus which he has never yet found and probably never will. No condition or circumstance can exert so favorable an influence upon life that some other condition or circumstance, real or imagined, cannot exert an influence still more to be desired. Thus man is never satisfied but strives ever upward as a result of the ever-increasing complexity of living matter, whose origin and whose destiny are both lost in the realms of the Infinite.

NORTH STREET AND WARD'S LANE.

DEFENSE MECHANISMS.

BY H. LAVESON, M.D.,

NEW YORK.

IN an article on "Lapsus of Memory" (MEDICAL RECORD, January 17, 1920) we considered an example of name forgetting and learned that this forgetting was really a phenomenon of repression and signified a protective effort against the reproduction in consciousness of the painful group of ideas with which the name happened to be associated. We may now consider another example of name forgetting and we shall immediately be introduced to a new form of defense mechanism.

Some time ago I was for a few days the guest of a certain married couple with whom I am intimately acquainted. One evening while my hostess, her husband, and I sat reading, she suddenly looked up from her book and asked: "Who was it that wrote 'Paradise Lost'? Was it Dante?" Her husband replied that she had confused the authors of "Paradise Lost" and of the "Inferno," and nothing more was said at the time. A little later, while her husband left the room, and, just as I was about to speak of her forgetting, she herself brought up the subject of psychoanalysis by asking me to explain a very annoying feeling which she had for some time experienced. This feeling consisted in a sense of aversion or repugnance toward all young men with light hair and blue eyes. She had been caused much discomfort by this singular antipathy, as a number of her husband's friends belonged to this type, and their frequent visits to her house always made her uneasy and unhappy. She realized perfectly that there was nothing in the character or behavior of these men to justify her peculiar feeling, but all her efforts to reason it away had been of no avail. There, obviously enough, was an affective reaction the source of which must have been in the Unconscious. No introspective effort on her part had furnished conscious data sufficient to explain it.

Pursuing the technique of free association, with which we familiarized ourselves in the article on "Psychoanalysis" (MEDICAL RECORD, June 5, 1920), "I asked her to fix her mind on the particular type of man she had described, and to relate all her incoming thoughts, expecting that in this manner she would produce descendants of the unconscious trends causing her strange aversion and sufficient to give some insight as to its nature. In response, she reported that she found herself thinking of a certain blond man with whom we are both slightly acquainted, next of another of much the same appearance whom also she knew only slightly. Then, after a short pause, she suddenly laughed, blushed, and said, with some confusion: "I just now thought of some one else." Having had from the start some rather definite suspicions as to the general significance of her antipathy to blond men, I asked at this point: "And towards this man you felt no aversion?" She at once admitted that I had guessed correctly, and then went on to relate what follows, which, as may be seen, affords an explanation both of her dislike of light-haired men and also of her failure to remember who wrote "Paradise Lost."

The man she had thought of was her first cousin. He is a very handsome specimen of the blond, blue-eyed type that later inspired feelings of repulsion. When she was about sixteen years of age she had seen a good deal of this man and had found herself falling seriously in love with him. But because of their close relationship and the fact that he was nearly ten years her senior, she had decided that it was very wrong in her to entertain any amorous regard for him. She had, therefore, resisted his attractions and endeavored to banish from her mind all sentimental thoughts concerning him. These efforts at repression were apparently successful for, as far as she was aware, he had ceased to be of any particular significance in her emotional life. But this complex, though it had become in great part unconscious, was by no means entirely deprived of expression. For instance, when, just before her marriage, she destroyed her collection of photographs of former admirers, she "forgot" to destroy the only picture she had of her cousin.

This forgetting we can hardly regard in any other way than as purposeful. Unconsciously she desired to keep the photograph. This little item, small as it is, has no mean significance. From it we are easily led to suppose that, in the Unconscious at least, more of her holophilic interest remained attached to the memory of her cousin than she was consciously aware of or ready to admit. In other words, her efforts to forget him, instead of annihilating this interest, had merely accomplished its repression. But no soon have we made this statement than we notice that her aversion toward all light-haired men is a trend diametrically opposite to that which we have just assumed to exist in the Unconscious. Are we therefore to suppose that because of this aversion we must have been wrong in assuming that toward that particular light-haired young man, her cousin, she had feelings just the opposed of aversion? Hardly. We can better explain the conditions by assuming that this aversion toward all light-haired young men was rather an over-development of those trends or counter-activations which produced the original

repression, and that the reason for this overdevelopment was that the repression was threatening to fail and required an increase of activity on the part of the repressing forces in order to prevent this. In other words, this overactivity on the part of these trends from the foreconscious served as a correction or antidote for what existed in her Unconscious. Thus consciously she wished to forget her cousin and was unwilling to care for him; unconsciously she still retained some love interest in him and wished to remember him. Her forgetting to destroy his photograph is an expression of the love trend. Her failure to recall who wrote "Paradise Lost" was an effect of the repressing trend. For it so happens that her cousin's name was Milton.

We have thus been introduced to a new form of manifestation of unconscious process, in addition to the dream and the forgetting of names—the two with which we are most familiar—that is to say, an exaggeration or overdevelopment of conscious and foreconscious trends serving as a defense against unconscious wishes of an opposite character, which threaten to break into consciousness. The somewhat analogous phenomenon which occurs in the psychic sphere, as has just been exemplified, goes by the same name, compensation. This may recall to us the phenomenon known in pathology as compensatory hypertrophy. A defect or deficiency in some organ is made up for by an overdevelopment and increase of functional activity on the part of the same organ or of its mate. Thus the effect of a leaky heart valve is discounted by an increase in size and strength of the heart muscle or an increase in the frequency of the heart's action; disease or removal of one kidney results in an increase in size and functional capacity on the part of the other kidney, etc.

One of the most commonly observed over-compensations is represented by the exaggerated anxiety so often displayed by neurotics over the health of some person close to them. Thus, for example, a neurotic girl is continually in a state of alarm concerning her mother. If her mother complains of being over-tired the girl thinks this presages an apoplexy. If the telephone rings while her mother is out, she thinks this is a message from the police saying her mother has dropped dead on the street. If she hears a noise during the night, she interprets it as her mother choking in a death agony.

In these and all other examples of over-compensation it is to be seen that the compensating motives belong essentially to the cultural, ethical, and acquired group of reactions and so to the foreconscious. The repressed trends which are compensated for are in the main more primitive, and are derived from instinct and the unconscious.

A mechanism of defense which is most commonly observed in the compulsion neurosis is that by generalization. Feelings which in the patient's consciousness are attached to a class or group really refer in the unconscious to a special one of its members. This is exemplified by the case of the young woman who had an antipathy to all blond, blue-eyed men, which was really founded on repressed wishes concerning one particular man of that type. In the psychological sphere in adult life, particularly in abnormal cases, occur phenomena which fail to distinguish between the ego and the non-ego. Thus on the one hand mental occurrences belonging to the ego are perceived by consciousness as of external origin, while, on the other, essentially external happenings are assimilated by the personality and made a part of the self. The former mechanism is known as projection, the latter is introjection.

The mechanism of projection is ordinarily one of defense. That which is perceived as of exopsychic origin represents trends or ideas which are painful to the conscious personality of the individual and out of harmony with the ruling impulses of the foreconscious. A completely successful repression such as he might desire would drive them entirely from the sphere of conscious perception; projection represents an effort at repression which is only partially successful. Failing to accomplish obliteration of the disagreeable presentations, the repression does succeed in more or less completely preventing the recognition of ownership. The presentations are then seen as of external origin, not as manifestations of tendencies of the individual himself.

An illustration of a very common form of projection occurred in the case of a girl of eighteen who came to me suffering with attacks of intense pain in one side of her face. Her family physician and one or two other doctors who had seen her were not quite certain whether these pains were of organic origin (tic douloureux) or psychic, that is to say, hysterical; and she was sent to me to have this question settled and, should the condition prove to be one of hysteria, for analytic treatment. When, after the first examination, I intimated to the girl and to her mother that the malady was not organic, the young woman became very angry, and both to me and later to her family expressed in no uncertain terms her very great contempt for me in not being able to recognize an out-and-out organic disease when I saw one. Nevertheless, she came to me for treatment and I was finally able to establish that her extreme emotional reaction against my view as to the nature of her pain was essentially a defense against the projected knowledge that I was right.

For it appeared that these attacks of pain came on when the young woman was indulging in erotic day-dreams, and then only; that she never had them apart from these dreams; that they lasted only as long as she kept on dreaming, and that she could at any time stop them by stopping the day-dream. Thus she had every reason to know that they were of psychic rather than of somatic origin. She was a Catholic and she knew that if she were to confess to the priest that she was having such phantasies he would tell her they were wrong and that she must stop them, a thing she was unwilling to do. As a way of evading this, her mind formed a compromise in the shape of the pains, which served the purpose of a punishment and a penance for the phantasies she regarded as sinful, and thus, in her opinion, to a certain degree absolved her from the obligation of confessing them and from the sin of not doing so.

What she attacked as a manifestation of my stupidity was really a projection of her own unwilling knowledge that her pains were not organic.

The most elaborate examples of projection are furnished by paranoia or major psychoses of the

paranoid type. I will give some brief examples of cases approaching the paranoid type.

A young woman student had at various times a number of delusional attacks which invariably began with her becoming attracted by some one of her professors. She would for a time talk a great deal about him, or how able and attractive he was, but without intimating that she was falling in love with him. Then she would begin to think that he was falling in love with her. This would seem to please and amuse her at first, but soon she would get the notion that he was hypnotizing her, and her pleasure would be succeeded by anger. She would complain that through hypnotic influence he was putting into her mind all sorts of erotic phantasies about him, that against her will he compelled her to masturbate with him in mind, that by telepathic suggestion he gave her impulses to come to his apartment, to have sexual relations with him, etc., all of which would get her into a state of great rage and excitement and she would have to abandon her studies. Thereupon the attack would gradually subside, only to be repeated in connection with some other teacher when she resumed her work.

It is apparent that this patient's delusional ideas were nothing but a projection of her own erotic interests in her teachers. What she felt as an hypnotic or telepathic influence brought to bear upon her from without was simply an externalization of her own desires. Her anger against the teachers represented her pathological resistances against these desires. Presumably had she been able to regard her sexuality in a normal way, as something perfectly legitimate and wholesome, what appeared as delusional attacks would otherwise have been ordinary love affairs.

The mechanism known as introjection is a process almost the reverse of that of projection. Where in the latter case the individual narrows his ego to a degree that processes actually belonging to it are perceived as of external origin, in the former he broadens the self to include within it what really belongs to other persons or objects. Thus, for example, that which happens to some other person causes him to feel or behave as if it had happened to him instead. This involves something more than ordinary sympathy. There is a definite, though usually unconscious sense of oneness or continuity with the other person. For this reason the phenomenon is commonly known under the term Identification.

The phenomena of introjection or identification are very common and essentially normal. It is only when carried to extremes that Identification becomes abnormal. It is, for example, a normal part of love. He who loves identifies himself with the love-object, and that person's pains or pleasures, successes or failures, honor or disgrace become in a measure his own. It expresses a sort of recognition of this love identification when we say of a married couple that the two have been made one.

We identify ourselves not only with loved persons, our friends and the members of our families, but also with things essentially impersonal or inanimate, our possessions, our country, its emblems, customs, institutions, etc. Thus we have a sense of identity with our house, our dog, or our automobile, and see in them virtues peculiar and different from those of the houses, dogs, or automobiles belonging to other people and which, in all tangible respects, are equal or superior to our own. The resident of New York or Chicago experiences a glow of personal pride on listening to some comment on the greatness of his city, or the dweller in the country may feel a flash of resentment on hearing a slur at country customs or country manners, even though he is thoroughly sophisticated and unprovincial.

We have also a great tendency to identify ourselves with people of importance who excite our admiration but whom we do not, in any ordinary sense, love. Such identifications usually correspond to a wish fulfillment. The inmate of an insane asylum who proudly informs us that he is Alexander the Great and conquered the world, or that he is Jesus Christ and saved it, is merely displaying an exaggerated form of the same kind of identification which enables us to find pleasure in such a statement as that our handwriting closely resembles ex-President Roosevelt's. Identifications of this sort which often lead to imitation have much to do with the rapid spread of fads or fashions when once adopted by the great or near-great.

An example of identification is as follows: I was treating a young man for homosexuality and during the course of one of the early visits he recalled that shortly after puberty there was a time when his feelings toward girls had been quite normal, but that his mother had so vigorously opposed all his interests in the opposite sex that after a year or more of struggle with her he finally gave in, and thereafter had only homosexual attachments. After having lived over again during this visit the bitter conflict he had had with his mother, which until he spoke of it on this occasion had for the most part faded from his mind, he remarked that he felt this discussion meant a great step toward recovery. He added that before he began the treatment he had had a feeling that we would suddenly come upon some discovery, whereupon he would all at once be well, and he now felt that the recollection of this warfare with his mother was that which he had been expecting. Upon my asking him what gave rise to this expectation, he replied that probably it was some case that he had read about but could not at the time recall.

Substitution.—Thus through compensation, which means quite as much libido directly against another object when it is obstructed by one object, we necessarily make use of substitutes. In other words, a strong desire is for some definite thing, unless it is for promiscuous muscular activity, and then kicking or running or swimming will satisfy. But it is a familiar human experience that when we want any specific thing it is possible to transfer that desire to some other thing. In this case we do not so much compensate as substitute. Generally a compensatory mechanism is a reaction in consciousness to an unconscious stimulus, while a substitution is the replacement of one thought or act in consciousness by another thought or act in consciousness. Furthermore, the term compensation is more extensive, that is, a long and complicated course of action may be called a compensation mechanism, while a single idea or mannerism of action—in other words, a small unit of activity is likely to be called a substitute formation.

Both compensations and substitutions are mediated through mere displacements of ideas. One idea displaces another in the mind and one idea is substituted for another idea as the goal-idea of a desire. This is not the same as saying that one idea follows another in the mind, each idea giving way before, and in that sense being displaced by, its successor. That would be a purely descriptive statement of what actually takes place in the mind because our stream of consciousness is never other than one idea following another. But a displacement or a substitution is an idea which takes the place of another idea in the mind at all times when that second idea, which we might call the original idea, would naturally (that is, if there were no repressions) appear in the mind. The original idea is a banished idea, not allowed to enter consciousness, and, as if it had a desire of its own to enter consciousness which it could satisfy vicariously, it sends its representative or proxy to act for it. Thus in displacement is implied an inability of the idea which is displaced to enter consciousness, together with its being unknown for what it really is and frequently there is implied a power of the displaced, covered, shrouded, masked idea to work, in the unconscious physical ill on the individual for whom it is a masked idea, due no doubt to the individual's consequent inability to adjust it to the remainder of his personality, which as he cannot see it, he is unable to do.

While one idea may be substituted for another as the goal-idea of a desire, the desire remains the same, not in content but in strength. Heine said that the French put as much energy into their pursuit of liberty as ardour into the affection for their chosen brides, while the Germans look upon liberty as they do upon their aged grandmothers. A man may devote his entire energy, which means his entire libido, to an abstract cause, or he may consume it in the love of a fair mistress. He may also, if the fair lady has rejected him and he finds no physical outlet for his excited emotions, spend them upon himself.

Displacement.—In identification and compensation we have seen a conscious thought displacing, or substituted for, an unconscious desire. Displacement is the generic term describing these substitutions of conscious thought and action for the natural instinctive unconscious thoughts which, though continuously pushing forward toward consciousness, are transformed in such a way that they are acceptable to the social conventions of conscious life. The thought and action of which we are conscious in ourselves and in others is invariably a displacement, a disguise under which the unconscious wish passes the censor and enters consciousness, a disguise without which it would be opposed. Only those thoughts and actions which are vigorously opposed as immoral when they enter consciousness, as they do occasionally as crime, heresy, etc., are the natural and undisguised unconscious wishes.

The classroom actions of the pupil are disguised or substituted actions in almost every case. And we are constantly requiring the pupil to make substitutions in his own action for the actions which his unconscious wishes would cause him to perform. In a sense, that is what school and education are for. But we reason that a superimposed substitution will have the same good result as a naturally developed one. Here is an instance:

It is quite true that a middle-aged man may sit gladly for hours (but not every man, at that) with a pen in his hand writing in a book and an almost infinitesimal proportion of men will write books which will have an influence on the acts of their fellow men. But to think that the influential words are caused by the sitting still is an evident fallacy, and yet that is exactly what we are doing in schools everywhere. The position in which we put the pupil is analogous to that of the middle-aged writer, before a desk and holding a pen, and the reasoning is exactly that of the savage who makes an image of his conception of a god and puts food before it. The savage thinks, "This image will eat this food and be pleased with me and grant me a favor exactly as I was pleased and did a favor for some one who set food before me."

We seem to have reasoned the same way. Just as good may come from a mature man sitting at a desk, so will good come from the immature man sitting at a desk. And this is a mental displacement (identification) just as erroneous, but just as dynamic psychologically because it has produced the present classroom requirements, as is the identification which the pupil makes of the teacher with the stern father or mother, or which the teacher makes of the pupil in identifying him with a previously experienced disorderly one. Similarly when a nervous woman comes to a physcian for treatment and one of the symptoms is an exaggerated solicitude for her moth or her children, we have another displacement. Like all unconscious displacements, it is the substitution of one idea for another. In the case of the nervous woman she replaced desire which was in her unconscious with its opposite anxiety in her conscious life, and by the strength of her solicitude she expressed the real depth of her unconscious desire that her mother should die. By the sternness with which we repress the movements of the child do we similarly express the depth of our unconscious desire to let him give full play to his instincts and develop them in a rational manner The exaggerated concern of a daughter for her mother's health or of a mother for that of her children has frequently been found to be a conscious overcompensation for the opposite wish in the unconscious. I think our present insistence upon uniformity and silence and motionlessness on the part of the school child is similarly an overcompensation for our real unconscious feeling that they need to move more than they do. And, of course, the thing works out in the opposite direction. The child overcompensates for his unconscious desire to neglect lessons by an occasional over-vigorous spurt of accomplishment.

It may be said that a noticeably strong conscious tendency in any direction is likely to indicate the presence of an opposite tendency in the unconscious, much as a convexity on one side of a thin metal plate corresponds to concavity on the other side. And in each case it is really the same force which produces the unevenness. Any unevenness in character, or idiosyncrasy or eccentricity is thus seen to here be the work of unconscious forces, the conscious form in which they are displayed almost invariably being a displacement of some sort.

Here we have reasoning by analogy carried out in a psychological and not a logical manner, and commit all the blunders which can be committed in so doing. Displacement is technically defined as the using of the wrong ideas with the wrong emotions, or vice versa, the psychical putting of things in the wrong place. When the displacement reaches an extreme, as it does in cases which psychiatry calls anxiety hysteria, the emotions which properly belong to certain ideas are taken away from those ideas entirely. The ideas are themselves repressed into the unconscious, but the emotions, which cannot be repressed, are attached to other ideas which in normal persons are not associated with such strong emotions.

If, for instance, a person is excessively afraid of snakes or of thunderstorms or of tunnels or of dogs or what not, and has a fear of them which other persons ridicule and which neither they nor the timorous person can account for, then they exemplify this displacement between idea and emotion. Similarly, any complete inability on the part of any pupil to master a given task may be caused by a similar displacement. The emotions which are engendered by the task are quite disproportionate to it. Therefore, they belong not to it but to some other idea which, if the teacher knows enough, may be discovered and the excessive emotion may be disengaged from the task in question.

I do not mean to say that there should be no emotion, no excitement, no liveliness in the schoolroom. All of these are necessary, on the part both of the pupil and of the teacher. In the pupils the emotions are properly expressed in activity which necessarily results in noise in the undraped room. I refer only to the type of emotion which is appropriate and which is seen in all school rooms where real honest effort is being made. There is no objection to frequent bursts of laughter, if they are the result of the pupils' perception of relations of the subject matter, and not mere deriding the unsuccessful efforts of some supposedly stupid pupil. Of course, it is unfortunate that we have not yet arrived at the state of civilization where the physical activities can be more gradually tapered off and the sublimation of physical into mental energy is not authoritatively demanded at once.

I know a high school, for instance, where the first experience of the incoming student is being required to sit two hours and a half in the assembly hall, where absolute silence and motionlessness is sternly demanded, and the unfortunate child who forgets and talks to his neighbor is required to take a seat on the platform and be eyed by a thousand children as an example. I know of no house of public entertainment where people gladly pay money for a seat, in which the performance of two and a half hours is not broken three or four times and the audience is given an opportunity to relax. But in our present school system, so powerfully are we dominated by the silence of the printed page that we act as if we supposed that directed thinking could be immediately produced by suppression of the physical expression of the undirected variety, all the motions of most children belong in this class.

In adult human life many of the most intensely interested persons are intense in certain directions by virtue of a displacement of over-compensation. Antivivisectionists frequently by their activity show an over-compensation for unconscious desire to inflict cruelty, the significant fact being that whether they were consciously or unconsciously cruel, they would be equally concerned psychically with the idea of cruelty, an idea which, to the ordinary person, has been outgrown with the other infantile attributes. Militant feminists, when women, are frequently giving expression by their excessive militancy to an unconscious wish not to rule and be the equals of men but to be ruled and dominated by a man. Lynching is another expression in consciousness of an unconscious desire for cruelty. Few members of a lynching party, if interrupted, would admit that they took pleasure in the sufferings of the lynched person. They rationalize their actions as being of social value, saying that they wish to deter others, to hasten the slow steps of justice, etc.

Thus we see one of the apparent inconsistencies of humans clearly accounted for. The person with an intense, because not seasonably outgrown desire, which is yet unconscious, to inflict cruelty on man or animals gets a reputation for an equally intense aversion to cruelty, to which, up to the present time, society has given its approval. It is quite evident here that consciousness and the unconscious are working together, but in an inconsistent manner. The unconscious desires cruelty, but is satisfied with the contemplation of cruelty and the effects of cruelty in and on other persons. It is quite evident, also, where the displacement comes in, and that it is the displacement which enables the conscious and the unconscious mental activities to get on the same track. Cruelty is what the mind is craving. In the case of the openly cruel man who becomes a criminal there occurs, too, and without displacement, a uniting of consciousness and the unconscious in one direction, thus avoiding a conflict, but it is a direction inimical to society nad society checks it in what manner it can at present by jailing or killing the cruel one. In the case of the person who is unconsciously craving to inflict cruelty, there is a displacement. The mind feasts on cruelty, but, in order to gain the approval of consciousness, and of society, so that it can go ahead full speed, it displaces the infliction of cruelty from self to some other person. In the case of some surgeons the displacement is of another character, for instead of the unconscious satisfaction being derived from the cruelty itself, the satisfaction is displaced (though not misplaced) to a satisfaction derived from the good results of the actions which cause pain.

Sublimation.—When the surgeon displaces the gratification derived from inflicting pain onto that derived from the results of the inflicting of the pain, which are of advantage to society, he is sublimating a trend of the unconscious. This trend, if left unsublimated and allowed to come directly into consciousness as it does in the murderer, let us say, is opposed to society and renders him an outcast. The thoughts which precede the crime also segregate him from true relations with society even before the crime is committed.

Thus sublimation is seen to lift an individual up out of the narrow limitations of his otherwise isolated self, and unite him with his fellows on a plane

higher than that on which he would be living in solitariness.

Diffuse Displacement.—A form of displacement called diffuse displacement does indeed occur very commonly in normal life and quite as commonly in the schoolroom. It is the tendency to find fault with everything. The cause of it is a defect in the adult-finder. This depends upon the principle that it is impossible to see in the external world what does not already exist in the mind. This principle applies with peculiar aptness to one's inability to criticise anything in another person, without having in his own conscious or unconscious mental life the same defect as that criticised. This principle, too, if fully realized by all people, would finally cut out all censorious criticism from the social relations of all people. If we fully believed and clearly saw that we could never find a fault in another which we did not have in ourselves, we would then keenly appreciate the fact that every time we found fault with anyone we were advertising the existence of that in ourselves too. While there are doubtless many apparent exceptions to this principle, I think it is undoubtedly true in the broad aspects of human character. The displacement is the acceptance of the one wish for the other and the ignorance that in the second wish form the original wish is to a certain extent satisfied.

Realization.—A man who smoked more tobacco that he thought he ought to began to cut down on his cigars on account of expense. He preferred cigars to tobacco in any other form, but smoked a pipe for economy, getting, however, a certain amount of real pleasure from it. Though still longing for cigars, which he used to buy by the box, and of the ten-cent qualty, he persistently, after his resolution, refrained from buying a box of them, knowing that he would smoke six a day, a waste of money which he could ill afford. He would buy two ten-cent cigars on his way home and smoke one after dinner, keeping the next for next day's dinner. Then he would see this cigar after breakfast the next morning, and would smoke it. Thereafter he would buy only one ten-cent cigar. Later he felt so virtuous about this economy that he thought if he denied himself two cigars a day he might as well have a moderately good one, and would buy a fifteen-cent cigar. Occasionally thereafter he would omit a day for some reason, either that he did not happen to pass the usual cigar store or that he was in a hurry and did not want to take time.

Once he was met at the train by his daughter, who walked home with him. They had an errand on the opposite side of the street from the cigar store. As they started to cross, she said to him: "Aren't you going to get your cigar?" He took this as an excuse, as he did everything that came along, and bought one at another store they passed, but compromised with himself and bought a ten-cent cigar instead of a fifteen-cent one. The next day when he was trying to pass the cigar store the thought came to him: "You had only a poor cigar last night. You might get a fifteen-cent one now to make up for it."

He had occasional headaches, which his conscience suggested to him came from too much smoking. But he also had a slight indigestion now and then, and his desire for cigars suggested that the headaches might just as well come from the indigestion and have nothing to do with tobacco, and so then he would buy and smoke a cigar. It then came into his mind that if there was any doubt about it he could prove it by quitting smoking for a time and see if he had any headaches. The idea that the tobacco might also cause the indigestion never occurred to him.

Finally he became disgusted with the reasons which he was habitually giving to himself for smoking, and saw that any reason whatever was reason enough to induce him to smoke, and that as a matter of fact one reason was just as good as another.

The rationalizations of the cigar smoker above mentioned were conscious ones. He knew that in a sense he was fooling himself all the time. But the majority of rationalizations are, in the case of most people, entirely unconscious. People do not know that the reasons they give for a statement or an opinion or an action are dictated to them by their own unconscious, and that their apparent cogency is attributable solely to their congruence with the desires of the people giving them as reasons. If we realize the fact that most reasons are mere rationalizations, we shall soon clearly see that in nine cases out of ten the reasons assigned by persons for doing anything are not the real causes why they do those things, but are indirect expressions of the unconscious wish. It is quite enlightening to realize that if you are unacquainted with your own unconscious, not a single reason you can possibly assign for anything you think, say, or do is the real cause of your thinking, saying, or doing it. The real cause is the unconscious wish of which you cannot possibly, without a thorough study of your own unconscious, be aware in the least degree. Only after a thorough analysis by an expert analyst can you trace any of your actions to their true cause. From this human tendency to rationalize every one of their acts emerges the fact that all people do what they want to and subsequently seek to align their actions with the principles of social living by assigning reasons for doing what they want to do. And from this it appears that whatever people are doing is what they want to do. This is the fact which is hardest to believe of all the facts recently discovered about the human soul.

511 East Eleventh Street.

INDUSTRIAL INJURIES AND FIRST AID.

A PLEA FOR THE IMMEDIATE TREATMENT OF THE INJURED.

By A. C. BURNHAM, M.D.,

NEW YORK.

It has been estimated that there is a shortage of more than 6,000,000 wage earners in the United States at the present time. This combined with the fact that since 1914 a large portion of the population have been either actually engaged in war or actively employed in the production of war supplies, has given rise to a state of under-production which is now in the acute stage. It is to be hoped that the peak of under-production and consequent high prices has been reached, but it is certain that the reconstruction process will be a slow one and normal production cannot be reached for several years.

What part is the physician to play in the process of readjustment? Medical men are not producers in the ordinary sense. They are chiefly consumers of what other people produce. However, they may help to increase production indirectly through their relation to the health of the rest of the community and therefore it lies in their power to play an important part in the economic readjustment, if they make proper use of the opportunities which are presented to them.

The necessity of effective medical care in the efficient functioning of the industrial machine is shown by a recent statistical report of the Pennsylvania Department of Labor and Industry for the year 1918. During that year in the State of Pennsylvania alone there was a total of 184,844 accidents, of which 3,403 were fatal. These figures representing the accidents for a single State indicate that for the United States the annual industrial casualties would far exceed the battle casualties of the recent war. The total accidents in Pennsylvania, including only those which represented a disability of two days or more, amounted to a labor loss of 2,767,471 days, and an annual wage loss of $10,286,872.

The number of accidents and the comparative figures for the industries chiefly concerned is shown by the following table:

ACCIDENTS IN THE STATE OF PENNSYLVANIA DURING 1918.

	Total	Metals and Metal Products	Mines and Quarries	Building and Contracting
All accidents	184,844	57,134	51,863	9,190
Fatal	3,403	557	1,266	221
Serious	53,783	15,091	15,327	3,069
Minor	127,658	41,468	35,290	5,900
Due to lack of safeguards	10,512	6,108	246	580
Days lost	2,767,471	759,517	811,657	147,357
Wages lost	$10,286,872	$3,164,629	$3,040,304	$601,136

It will be noted that the metals and metal products trade accounted for nearly a third of the total accidents and that "mines and quarries" were responsible for more than a third of all accidental deaths. Building and contracting which stood third on the list with 9,190 accidents showed a total wage loss of over six hundred thousand dollars. The smallest loss was shown by tobacco trades where there were 136 accidents with only one death. The public service, which is not a trade in the ordinary sense, showed a total of 32,625 accidents with 745 deaths.

From the viewpoint of the physician the nature of the injury is of considerable interest. According to the classification of the Pennsylvania Department of Labor and Industry the nature of the injury in all cases was as follows:

NATURE OF INJURY

PENNSYLVANIA STATISTICS 1918.

	All Accidents	Fatal Cases
Crushes and bruises	71,831	1,414
Cuts and lacerations	51,021	467
Fractures, sprains and dislocations	36,713	795
Burns and scalds	12,394	361
Blood poisoning	4,045	26
Punctures	4,997	22
Hernia	1,576	22
Unclassified	2,267	296

It is hardly necessary to say that by the proper use of safeguards a considerable portion of these accidents might be prevented. The official figures state that 10,512 accidents were "due to lack of safeguards" but it is probable that the actual number is even greater than this figure. There is a strong movement at the present time for the conservation of the human machine and there is, as a consequence, a steady increase in the use of safeguards on power machines, the use of which is causing a steady decrease in the number of preventable accidents. However this is not a problem for the physician but is a question to be settled by the safety engineer.

While the industrial surgeon may indicate the fact that certain machines are responsible for an abnormal percentage of accidents and should consider it as part of his duty to indicate the occurrence of such figures to the safety engineer, he is concerned chiefly with the care of the injury after it is received. It is therefore the immediate care of industrial accidents from the surgical standpoint which it is desired to emphasize in this paper.

It is widely established at the present time that the earlier an injury receives intelligent treatment the better are the chances of recovery and the shorter is the period of disability. This can be regarded as axiomatic and not open to discussion.

From the viewpoint of the physician the entire question resolves itself into a discussion of the value of the services of the volunteer assistant and the query whether or not the training of first aid assistants in factories, mines, schools, and other similar places is justified from a medical and economic standpoint.

Among physicians there are two views which are held generally: the first considers all attempts at volunteer first aid as meddlesome, apt to do as much harm as good, and holds to the belief that nothing at all should be done until the patient is seen by a physician; the second opinion is that simple first aid measures should be taught to volunteers and that immediate treatment should be given in every case.

The arguments in favor of what might be termed the "do-nothing" policy may be briefly indicated as follows: (*a*) In some cases the wrong treatment is given and harm is done. (*b*) The patient is given a false sense of security and consequently some cases requiring further treatment do not report to the surgeon. (*c*) It tends to increase home treatment. (*d*) There is little necessity of early treatment in most cases and time devoted to instruction in first aid is wasted.

The arguments in favor of first aid by volunteer assistants may be summed up as follows: (*a*) Occasionally (even if very rarely) a life is saved by early intelligent treatment. (*b*) The number of cases of infection is greatly diminished in factories where first aid is intelligently carried out. (*c*) If volunteer assistants are carefully trained errors in treatment are very rare. (*d*) Emphasis on first aid tends to emphasize dangers and thereby definitely decreases the total injuries in a given plant. (*e*) Time devoted to instruction is paid back in terms of diminished disability and labor turnover.

The American Red Cross, in its campaign for the extension of first aid as a peace time activity, is emphasizing the fact that instruction to be effective must be thorough, extending over a period of at least fifteen hours. Students are taught simple methods for the immediate treatment of

emergencies but they are taught that in every case the treatment is essentially an emergency treatment and is not intended to supplant the services of a physician.

In many industrial plants it is a fixed rule that every injury no matter how trivial must receive first aid treatment at once following which the patient reports to the company surgeon. It is reported that where this is carefully carried out there is a marked reduction of secondary infection and consequently a diminished disability rate due to accidents. The large number of injuries to the fingers indicates in part the proportion which would naturally be suitable for early first aid treatment.

PART INJURED
PENNSYLVANIA STATISTICS
ALL ACCIDENTS 1918.

Fingers	37,265
Trunk	31,176
Hands	20,515
Head and face	16,474
Eyes	11,727
Arms	10,379
Legs	19,288
Feet	27,595
Toes	10,425

In teaching first aid it is as important to emphasize what not to do as it is to give methods of treatment. First aid kits should be as simple as possible so that errors in the use of drugs or dressings may be reduced to a minimum.

The use of iodine as an application directly to a wound of the soft part is fairly well established as the best method of first aid treatment. It has the endorsement of a large number of surgeons of wide experience in industrial surgery. It is possible that there are other methods which are as good or better, but they are little known and they are absolutely unknown to most volunteer students of first aid. Iodine is widely used, its use is fairly well understood even by those of sligt general education, and its irritating qualities on the eye or other delicate tisues are generally appreciated. Its use is so simple that the method of application is easily remembered. From the scientific and practical aspect the use of iodine has been fully justified by the results obtained. It will certainly kill many of the surface bacteria and in some cases all of them.

From an extended experience in the treatment of emergency cases the writer has concluded that, from a practical standpoint, the iodine dressing is much superior to any of the other forms of first aid applications for abrasions and wounds.

In applying iodine the wound should be fairly dry and the iodine painted into every part of the wound and on the surrounding skin for an inch or more. A three per cent. tincture is used. This can be prepared fairly accurately by adding roughly an equal part of alcohol to the official tincture of iodine. In teaching first aid to volunteer assistants it is well to warn them that the alcohol evaporates so that the tincture tends to become stronger. This has been avoided in a certain type of first aid boxes by the use of individual iodine ampules, one of which must be broken for each treatment. Unfortunately they are rather expensive and tend to discourage the use of iodine for small abrasions and cuts, the treatment of which should always include the use of iodine even if the wounds are so insignificant that no dressing is required. In most cases it is better to have a small bottle of iodine in addition to the ampules. In inspecting first aid supplies the physician in charge should test the strength of old bottles of iodine by noting the color when a single coat is applied to the skin. If the color approaches a very dark brown the iodine is probably too strong. This is, of course, only a rough test but serves as a fairly satisfactory indication of the strength of the tincture.

Iodine should not be used in combination with other drugs as there are many combinations of iodine with other substances which are extremely irritating. The best known of these substances is mercury. If the skin is painted with tincture of iodine and then covered with a wet bichloride of mercury dressing a severe burn will result. The same is true of mercury ointment and other forms of mercurial applications.

In children, and occasionally in adults, even half strength tincture of iodine may cause blistering, but this is rare and does not counteract the distinct advantages of its use. In case severe burning is complained of after the use of iodine the excess should be removed with a swab dipped in alcohol.

In the case of burns the first aid treatment is less clearly indicated. Some surgeons still use carron oil which has the advantage of affording distinct relief from pain. Probably as good results are obtained from the use of boric acid ointment or even sterile petrolatum but the relief from pain is distinctly less. Some surgeons prefer picric acid either in weak solutions or in the form of picric acid gauze.

When the surgeon can be reached within a few minutes it is perhaps better to have no dressing at all applied to the burned area by the volunteer first aid assistant, or at most only a dry dressing of sterile gauze. The application of ambrine or other similar substance is too complicated for first aid use.

The use of the tourniquet by first aid workers must be carefully supervised. Too often the tourniquet is incorrectly applied so that only the venous flow is blocked while the arterial flow is unhindered. The result is that the tourniquet increases the bleeding rather than diminishes it. In teaching first aid emphasis should be placed upon the dangers of the tourniquet if wrongly applied and the fact that it should be used only by those who fully understand the method of application. The use of the tourniquet with a pressure pad over the artery has been practically abandoned because it was found that it was seldom, if ever, correctly applied by the first aid assistant.

First aid for fractures should be limited largely to measures for the prevention of further injury. Elaborate splints and plaster work have no place in first aid training. Simple splinting such as was taught to the Sanitary Troops is of considerable use, for in many cases the patient must be transported a considerable distance before a physician can be seen. Emphasis should be placed upon the dangers of constriction of the part and especial efforts made to present in a logical manner the mechanics of the treatment of a few or more common fractures.

As a rule factory employees are interested in

emergency treatment, and it is believed that it is within the power of physicians to stimulate this interest to a considerable extent. Cooperation of employer, employee, and physician should make for decreased disability which in turn would mean a diminished labor turnover and decreased wage loss.

Industrial managers must be taught, and the teaching must be done largely by physicians, that the health of the employee is one of the indispensable factors in the life of the community and that every effort must be made for its preservation. The development of safety and that of first aid go hand in hand and are both of extreme importance during the present period of labor shortage and underproduction.

IMMUNITY TO TUBERCULOSIS AMONG WORKERS IN SULPHUR DIOXIDE.

By F. TWEDDELL, M.D.,

GREAT NECK, N. Y.

HAVING used sulphur dioxide with good results in the treatment of pulmonary and laryngeal tuberculosis for the past four years,* I thought it might be of interest to know if men who were exposed to this gas in industries where it is used were benefited or harmed thereby. I was particularly anxious to obtain these data, because so many physicians consider sulphur dioxide injurious to the tissues of the lungs.

I therefore obtained a list of nine chemical companies using sulphur dioxide, chiefly in the dyestuff industry. Later I obtained the names of eighteen of the largest storage battery companies which use sulphuric acid in their charging plants. The action of sulphuric acid fumes is essentially the same as sulphur dioxide, for when sulphur dioxide comes in contact with water or the moist mucous membranes of the larynx or the lungs, it forms sulphurous acid (H_2SO_3) which is very unstable and has a great affinity for oxygen, ultimately forming sulphuric acid (H_2SO_4).

Through the U. S. Geological Survey Department I received a list of twenty-two of the largest manufacturers of sulphur dioxide and sulphuric acid. Circulars were sent to all of these forty-nine companies asking for the number of men employed, who were habitually exposed to sulphur dioxide or the fumes of sulphuric acid, and for the number of cases of tuberculosis noted.

Five companies did not reply. Six companies could give no data. Of the thirty-eight companies which answered the circular, thirty-one never had a case of tuberculosis among their men. Nine companies omitted to mention the number of men employed, but gave data in regard to tuberculosis.

The remaining twenty-nine companies employed 11,085 men, of whom 7707 men were habitually exposed to sulphur dioxide or sulphuric acid, and 3378 men were not constantly exposed. Fourteen companies reported being in existence for an average period of over twelve years each. Only twenty-two cases of tuberculosis were noted, that is to say during the entire period of existence of all these thirty-eight concerns.

* See former paper: Experiments with a new and most efficient remedy for pulmonary and laryngeal tuberculosis, MEDICAL RECORD, Dec. 21, 1918.

An analysis of these twenty-two cases shows:

Seven were suffering from tuberculosis at the time that they were engaged; of these, two died and two got perfectly well.

Two were suspected of tuberculosis when first engaged.

Five cases followed the epidemic of influenza.

One case followed injury and amputation of leg (now improving).

One case contracted tuberculosis ("a colored man of rather careless habits and inclined to dissipate"). He died.

Six cases reported, but it is not stated when contracted. One company picked out three of these men during the course of two years among a total of 3378 men, who were not habitually exposed to sulphur dioxide.

Omitting the seven cases who were tuberculous before employment, the two suspected cases, and the five cases following epidemic influenza, we have only eight remaining cases to account for.

Eight cases among 11,085 men during an average period of over twelve years is a negligible quantity, about one case in 16,627 men per annum.

The comments and observations of some of the managers of plants are instructive:

One manager[1] reports: "The writer had several years experience in England in similar work, and it was the common opinion amongst the men that those working with sulphur dioxide were not only more free from tuberculosis troubles, but also from ordinary coughs and colds. Of course this was only the men's idea and was not scientifically checked up as far as we know."

Another manager[2] says: "The writer has been connected with the heavy chemical industry for the last twenty years, most of the time associated with industries manufacturing sulphur dioxide. The general health of the men operating around sulphur dioxide was always very good, and we had men who had worked in sulphur dioxide as much as forty years. We never considered sulphur dioxide a bad gas to be associated with. During the entire period I do not recall having seen or heard of any of our men being affected with tuberculosis. Two men were connected with the plant for over fifteen years; both were fat and robust.

"There is rather an interesting condition that we observed during the winter (1919-20), when men from all other departments were home sick with influenza, there was not a man in this department who was so affected. Frequently fumes of sulphur dioxide are very strong in this department, but thus far none of our men have ever suffered any inconvenience (ill effects) from same.

"It may be of interest to you, that in a certain sulphuric acid plant, in which the chamber process was used, birds and pigeons nested in the tops of some of these plants in which there was considerable sulphur dioxide, but it seemed to cause them no inconvenience."

Another manager[3] states: "Workers in this division (storage battery acid department) did not suffer from influenza nor any pulmonary disorders."

Another manager[4] writes: "We find that after a man works in our acid department for any length of time, he begins to take on weight, one man in particular gained fifteen pounds in two years."

Another[5] states: "Whether it is a superstition or an actuality, the fact remains that our employes have the idea that the acid fumes do them no harm, but on the contrary have a tendency to act as a preventative of lung troubles. We do not know whether there is any basis for this conclusion or not, but we do know that to our knowledge there has never been anyone in our employ to whom exposure to acid fumes has resulted deleteriously."

Another manager[6] states: "We understand from outside sources that sulphuric acid fumes will cure tuberculosis."

Another manager[7] states: "Our superintendent reports that as far as his observation has gone, lung trouble of any sort is almost unknown among smelter and acid men."

Another manager[8] states: "In fact, I have always understood that men employed in the fertilizer industry are particularly free from this disease (tuberculosis)."

Another manager[9] states: "To date we have no record of ever having had a case of tuberculosis. Our investigation, however, reveals the fact that our oldest sulphuric acid employee, in all his experience with sulphuric acid operations, had seen but one man suffering with tuberculosis, and this man while working around the acid appeared to show improvement. In general, our experience would seem to indicate that sulphuric acid fumes are in no way detrimental to the health of persons suffering from tuberculosis."

Another manager[10] states: "A friend of mine was sent to a sanatorium for the treatment of tuberculosis, and upon his return was told by his doctor not to seek employment in an acid plant or fertilizer factory. He did not obey the doctor's orders, and took up the fertilizer and acid work. To-day he is one of the most healthy looking specimens of humanity I have ever seen."

Another manager[11] states: "The writer's experience in the chemical industry during the last sixteen years has led him to a very definite conclusion that sulphur dioxide does give workmen who are exposed to it continuously practically complete immunity to tuberculosis. The concentration to which men are exposed is usually somewhere between two and eight parts per million; and gas at this concentration has no destructive action on tissue, but seems rather to have a distinct bactericidal action, such action being the underlying cause for the immunity of the men to tuberculosis.

"In this general connection it is usually assumed in the chemical industry that chlorine is a beneficent agent, inasmuch as men exposed to its fumes do not contract any of the forms of influenza, and in fact the general run of zymotic diseases. The writer had some experience in a chlorine factory, which led him to the conclusion that while chlorine did give immunity in certain cases, it did not provide immunity against tuberculosis, as several workers in the chlorine department were affected with tuberculosis.

"Since I wrote you I have made inquiries of other acid manufacturers, and while no accurate records have been kept, it seems to be an accepted fact that none of the acid makers in this vicinity has any recollection of any of the men engaged in sulphuric acid manufacture contracting tuberculosis."

Another manager[12] states: "My personal experience leads me to the belief that sulphur dioxide, if not a curative, certainly acts as a preventative in tuberculosis. I recall especially the case of an elderly man, whom I employed as a burner man in 1887-88. This party was by trade a miller and had been running a country mill practically all his life. He gave up this work on the advice of his physician, and when I employed him, his lungs were undoubtedly affected. I employed him as a burner man, when he was exposed daily to a certain amount of sulphur fumes, and in the course of a few years he became entirely well. Later on I lost track of him, but I happened to know that he lived until a few years ago, and his death was not caused by tuberculosis. On the other hand, in an experience extending over about 34 years, I cannot recall a single case where a man employed around sulphuric acid works either contracted tuberculosis or died from that cause. I do not think that sulphuric acid has any effect one way or the other, but am decidedly of the opinion that sulphur dioxide certainly seems to act as a preventative."

A medical director states that he was formerly in a locality for two or three years, where a large quantity of sulphuric acid was made, and never heard of a case of tuberculosis there. One foreman who was employed for twelve years in this plant "has been almost entirely free from ordinary colds, and as soon as the workers become accustomed to the fumes they seem unusually free from colds or bronchial conditions."

Of the 22 cases of tuberculosis reported, three especially interested me. All three were chronic cases: A medical director reports that a tuberculous worker had shown no change in his condition for several years. Another physician reports that a tuberculous worker in the plant had been under observation for ten years (apparently unimproved). The third case was reported by the manager of a plant. A tuberculous worker was employed for four years in the plant, and died of tuberculosis three years after leaving the company.

There was apparently no improvement in the above cases. It is my opinion that these men were suffering from fibroid phthisis. I wish especially to emphasize this, for in my experience I have noted that patients with this form of phthisis show no improvement under treatment with sulphur dioxide. And from these observations I claim that the tubercle bacillus of fibroid phthisis is of a different type, analogous to the different types of pneumococci.

Summary.—1. The percentage of cases of tuberculosis among workers around sulphur dioxide and sulphuric acid is negligible.

2. Sulphur dioxide and the fumes of sulphuric acid appear to act as preventatives of tuberculosis, and possibly as a cure in incipient cases, with the exception perhaps of fibroid phthisis.

3. I am continuing investigations along these lines and would welcome additional data from any source. The data already collected cannot be ignored.

LIST OF COMPANIES WHOSE REPORTS ARE QUOTED.

1. Amalgamated Dyestuff & Chemical Co., Newark, N. J.

DIAGNOSIS OF CANCER OF THE RECTUM.

By CHARLES J. DRUECK, M.D.,

CHICAGO, ILL.

PROFESSOR OF RECTAL DISEASES POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, RECTAL SURGEON TO PEOPLES HOSPITAL.

CANCER of the rectum may be confused with a number of other conditions, benign, inflammatory, and traumatic, occurring either within the rectum or in the pelvic structures.

Epithelioma at the anus may be mistaken for fissure, condyloma, tuberculous deposits, actinomycosis, or an ulcerated hemorrhoid.

A malignant tumor is to be suspected within the bowel in any adult when a bloody diarrhea exists that cannot be accounted for by parasites or bacteria. Digital examination is sufficient only if the tumor is low down (within 4 inches from the anus). Ten inches may be inspected through the proctoscope and even a greater length may be examined with a bimanual examination. Benign tumors as a class are soft, have pedicles, project into the lumen of the bowel, are movable, and do not invade surrounding tissues; while the malignant growths are more or less solid or hard, and spread out between the mucous and muscular coats of the rectum in such a way that they invade several square inches of the bowel and yet project very little if at all into the rectum. All growths with a broad infiltrating base are to be considered malignant. Where secondary growths in other organs produce symptoms before intestinal obstruction occurs the local symptoms may be obscured and the diagnosis clouded.

Scirrhus cancer if seen early presents through the proctoscope a stiffening induration on one side which closely resembles fibrous stricture, but the history of the trouble will differentiate the two. Carcinoma begins insiduously, whereas inflammatory stricture follows trauma, ulceration, or suppuration. Later, when obstruction begins, there occur colicky pains in the stomach or small intestine and occasionally sharp cutting pain in the region of the growth. Intense peristalsis above the mass produces intussusception. The location of the trouble is of much significance because fibrous stricture occurs usually in the rectum and rarely in the sigmoid, whereas, scirrhus cancer is uncommon in the rectum but is generally found in the sigmoid.

Medullary cancer presents a very different pathological and clinical picture. Constipation may not be noted, but in its stead a teasing tenesmus with a passage of flatus, mucus, and perhaps blood. Although the sufferer may defecate twenty times during the morning there is always a feeling of something left in the rectum. This diarrhea is most urgent in the morning and is spoken of as a morning diarrhea. The first passage in the morning is mostly mucus, pus, and blood, a little later there is a good fecal evacuation, but during the rest of the day the evacuations are gas and mucus accompanied with much teasing tenesmus. Hemorrhage is variable. Through the proctoscope is seen a red berry-like mass projecting from the side of the gut, with a pale areola of mucous membrane about it.

Encephaloid cancers break down and ulcerate early. At first the normal mucous membrane is movable over the growth, but it soon ulcerates; this degeneraton may occur at one or several places simultaneously and the mucous membrane is honeycombed with ulcerating spots through some of which the cancerous growth may protrude. Ulceration begins at the central or denser parts of the cancer and is not limited to the superimposed mucous membrane but invades the deeper structures and in some cases extends into surrounding tissues. While the periphery is advancing into new tissues the center is undergoing degeneration. Around the edges the new growth, together with the inflammatory reaction, raises the border and gives the ulcer a crater-like appearance. The muscular tissue seems to have greater resisting power and prevents somewhat the extension of the ulcerative process. The extension, however, progresses irregularly and creates a ragged edge. If the tumor is high in the sigmoid or in the colon the diarrhea may be so annoying as to make the proctoscopic examination unsatisfactory without first thoroughly irrigating the bowel.

The encephaloid cancer may be mistaken for the benign adenoma and papilloma which occur quite frequently and are important because they are sometimes very difficult to diagnose, and so frequently carcinomatous changes occur in the benign tumor if it is left or a cancer recurs when the apparently benign tumor has been removed. Benign growths are usually attached by pedicles, but if they have broad bases they are never indurated. Inasmuch as these tumors are so liable to contain malignant cells or to develop malignancy later, I never place much credence in laboratory findings of bits removed from the tumors, because part of the tumor may be benign and another part may be malignant. Benign fibrous stricture due to nonspecific ulceration, and when following long after some previous rectal trouble is most difficult to differentiate. It is smooth and regular in contrast with the irregular, nodular, and rough appearance of cancer. Of course, the history of the case is entirely different, as the traumatic stricture produces no symptoms other than obstruction.

The congenital stricture is frequently unobserved until the affected child eats solid food and the stools are formed, but it is almost always recognized before puberty. The symptoms are those of obstruction in an otherwise healthy child, and of long standing, whereas carcinoma does not occur until adult life.

Syphilitic lesions in the rectum may be mistaken for cancer, particularly the encephaloid cancer. Chancres are very rare above the anorectal line. Mucous patches occur about the same time as the macular eruption on the skin. Both these lesions have a tendency in ulcerating to follow the blood vessels and lymphatics, so that the ulcer spreads

upward rather than laterally. There is considerable discharge having the peculiar chancre smell. It is very different from that of carcinoma.

Gumma begins in the connective tissues and if seen early the mucous membrane is free above the tumor, which is round and elastic, and may be as large as an orange. Later it undergoes fatty degeneration and ulceration and the cicatrix may cause stricture.

In the proliferating proctitis, fragile villous teats hang from the mucous membrane. There is an abundant discharge of mucopus. The granulating mass is soft and its base is limited to the mucous membrane, but does not infiltrate below. The growth spreads all over the rectum and is not limited to one part.

Syphilitic stricture in the lower rectum can hardly be mistaken for cancer because the history is much more chronic, the infiltration is more diffuse and lacks the hard, nodular, feel of carcinoma, the ulcers are more shallow and have smooth edges, and finally the history of syphilis can usually be elicited. In any suspected syphilitic lesion the spirochete should be sought.

Acute and chronic colitis accompanied with hemorrhage and loss of weight and the usual spasm of the bowel may simulate cancer, but the bosselated inflamed mucous membrane covered with blood, mucus, and pus as seen through the sigmoidscope will clear up the diagnosis.

Tuberculosis is more difficult to differentiate, especially if involving the anus, but there is usually evidence of tuberculosis in other parts of the body. It rarely causes obstruction, as the infiltrating deposit ulcerates early and the ulcers are shallow with undermined edges. The tumor is small and is due to inflammatory exudates and the involving of the glands. Microscopically, tuberculous inflammation and bacilli may be found.

Actinomycosis of the bowel must be thought of, although 60 per cent. of the cases of actinomycosis are confined to the neighborhood of the appendix and cecum and may closely simulate appendicitis (Lynch: Disease of the Rectum and Colon).

Among the less common conditions, which, however, must occasionally be differentiated are traumatic stricture, which is felt as a dense, sharp, constricting ring and presents no symptoms other than those due to obstruction; chronic appendicitis, especially if the mass is located on the right side, which an opening for operation will decide; fecal impaction which lacks the infiltration and really has only the one symptom of obstruction, and finally extrarectal growth and inflammation which occlude the lumen of the bowel by pressure or involve the coats of the tube by extension. Cancerous growth of the sigmoid may be palpated through the abdomen often before it produces obstruction. Carcinoma may be mistaken by its symptoms for chronic dysentery, because of pain, tenesmus, and bloody and mucous stools, but careful digital and sigmoidoscopic examination with the assistance of the fluoroscope's screen or *x*-ray picture will clear up the condition.

Hypernephroma or prolapsed kidney may simulate a tumor of the bowel, but will be differentiated by finding blood in the urine and later by ureteral catheterization. The tumor in hypernephroma is behind the bowel thus affording a tympanic instead of a dull percussion note. The symptoms come on slowly with lumbar pain radiating to the abdomen and down the thigh.

Diverticulitis occurs in the sigmoid and may be mistaken for cancer. It usually produces a large tumor which can be palpated through the abdominal wall. Cancer, until late, does not present adhesions. Diverticulitis produces a tumor that clinically very much resembles cancer, but it occurs early. When the abdomen is opened, if a large tumor mass is found adherent, as is commonly the case in diverticulitis, it is quite probable the condition is not cancer, because cancer of the large bowel does not become adherent until late in the disease. The adhesions are due to infection. They cause obstruction and they do not require removal. Just passing around them with a lateral anastomosis does as well as the more severe operation of radical removals.

In any of these cases where the diagnosis is doubtful and an exploratory laparotomy is made, the incision should be made as for colostomy, so that if removal of the tumor is unwarranted, an artificial anus may be made at once.

Don'ts.—Don't attach undue importance to a patient's history of "piles," "indigestion," or "constipation," but insist upon a rectal examination in every instance.

Don't assume that the passage of bloody or slimy stools is due to dysentery. There may be cancer.

Don't assume that bleeding from the rectum points to piles. It may be due to cancer.

30 North Michigan Avenue.

QUININE IN THE TREATMENT OF HEMOPTYSIS.*

By JOSEPH E. STROBEL, M.D.,

HARTFORD, CONN.

Hemoptysis or bloodspitting is frequently the first symptom to call the attention of a person to the fact that he is in urgent need of medical care. In varying instances it has been passed by lightly and looked upon as a throat or stomach hemorrhage, when to the average physician it is almost pathognomic of pulmonary tuberculosis. These hemorrhages have a large degree of variance in amount, ranging from a streak to 1,000 cc. or more. The duration also varies greatly from a few minutes to days.

As to the cause of this fear-begetting symptom, many theories have been put forth. Some of them are over-exertion, ulceration of the wall of a blood vessel, loss of tissue which formerly supported the blood vessel wall, high blood pressure, mixed infection, and changes in the barometric pressure.

In looking over the literature at my command on the subject, I find quite a difference of opinion regarding the treatment of this complication. Some say there is little we can do, others that it matters not very much what we do, as a patient seldom dies from the immediate effect of hemorrhage, but on the other hand usually recovers. Among the great number of drugs recommended in the treatment of

*Read before the Hartford County Medical Society.

this symptom are morphine, ergot, alum, adrenalin, magnesium sulphate, blood serum, digitalis, salt, gelatin, and the nitrates.

Going back to the causes of this symptom, we can say that the first, over-exertion, can be practically ruled out, as all of the hemorrhages that have come under my observation have occurred in patients who have been resting or who have been in bed. Again a patient often comes with a story that some time ago he coughed up some blood and either continued at his work or returned to it in a day or two without any recurrence. High blood pressure can also be discounted very highly, as it was found at the Meriden Sanatorium that the blood pressure was low in some 15,000 or 20,000 readings and that immediately after the hemorrhage, even if it were a large one, the pressure would rise in some instances as much as fifty mm. Hg. In view of this we might say that a high blood pressure is the result and not the cause of hemorrhage from the lung.

Before the following experiment was carried out, we frequently had the disagreeable experience of group hemorrhage, or in other words, an epidemic of blood spitters. There would be as many as four or five patients all bleeding at the same time, and not infrequently a like number of patients in another building would be suffering in the same manner. In a great number of instances the result of this would be a spread of the disease into new tissue or a lighting up of a heretofore quiescent area or a remote pneumonia.

Assuming that the theory of mixed infection was correct I undertook to prove it and if possible to devise some method of procedure whereby this complication could not only be promptly cleared up but prevented. Fifty-four healthy full-grown rabbits were used. Into each one was injected subcutaneously ½ cc. of fresh bloody sputum from as many different patients and during different seasons of the year. The result was that fifty-one developed a lobar pneumonia and a pneumococcic septicemia, two developed a localized tuberculous abscess, and one an abdominal abscess from which a pure culture of streptothrix was obtained. Five of the fifty-one rabbits were controlled by a rabbit of similar weight receiving a similar inoculation but to which had been given fifteen minutes previously one grain of quinine sulphate intravenously. These controls were killed after two to three months, presenting all organs and blood free from tubercles and diplococcic pneumonia.

As a result of these findings our treatment of this condition has been changed accordingly. Patients coming to the sanatorium with history of hemorrhage or blood spitting, especially of recent occurrence, are given quinine every four hours in five-grain doses for one week. The symptom seldom recurs. Resident patients whose sputum is blood-streaked are given the same treatment. Patients who have hemorrhage are given the same dose but at shorter intervals. Nothing else is done so far as drugs are concerned. The patient is placed on liquid diet, kept in bed, and if it is comforting an ice cap is placed on the chest. Our results have been quite favorable. Hemorrhage has become a rare occurrence. When a hemorrhage does occur it clears up promptly and with little or no bad after-effect upon the patient.

Medicolegal Notes.

Practicing Without License—Sufficiency of Indictment.—The Minnesota Supreme Court holds that an indictment charging that, at a certain time and place, the person named therein did unlawfully practice medicine, and for a fee prescribe, direct, and recommend certain drugs and medicine for use and medicinal treatment of a certain named person without a license so to do, states an offense under the Minnesota statute of 1913. It is not necessary, under this statute, that the indictment negative the exceptions in the statute; such exceptions not appearing in the enacting clause of the act.—State v. Bohls, Minnesota Supreme Court, 175 N. W. 915.

Admission of Negligence Admissible in Evidence.—The Minnesota Supreme Court holds that in an action against a physician for negligence in treating the plaintiff's intestate, wherein the complaint fairly construed charged negligence in failing to ascertain his ailment, the defendant's statement after the patient's death, and in response to his mother's charge of incompetent treatment that he knew the patient had been treated wrong, and that he could be punished, was in the nature of an admission against interest relevant to the issue, and, in connection with other evidence therein, should have been submitted to the jury.—Thorkeldson v. Nicholson, Minnesota Supreme Court, 175 N. W. 1008.

Ruptured Aorta Due to Accident.—Where a workman operating a windlass has a hemorrhage from a ruptured aorta and dies, there being no direct evidence of extraordinary exertion suddenly displayed, it is held that his death is due to an "accident" within the Illinois Workmen's Compensation Act. The words "accident" and "accidental injury" within that act were meant to include every injury suffered in the course of employment for which there was an existing right of action at the time the act was passed; also to extend the liability of the employer to make compensation for injuries for which he was not previously liable and to limit such compensation. If an injury can be traceable to a definite time, place, and cause and the injury occurs in the course of the employment, it is accidental within the meaning of the act.—E. Baggot Co. v. Industrial Commission, Illinois Supreme Court, 125 N. E. 254.

Unlawful Practice of Medicine.—One who maintained offices where he treated any and all persons who might apply to him, for various and sundry disorders and diseases, for compensation, without having registered with the district clerk of the county, as required by the Texas Penal Code 1916, chapter 6, was held to be unlawfully practicing medicine, regardless of whether such person claimed to be a physician or a practitioner of medicine.—Black v. State, Texas Criminal Appeals, 216 S. W. 181.

Patient's Privilege as to Physician's Testimony.—It is held to be improper for the physicians who treated an injured person to accept employment as medical experts for the defendant in an action brought for the injuries by their former patient. It is also held that the fact that such injured person, being incapable of volition in the choice of a physician, is taken to a hospital where he is treated as a free patient, does not deprive him of his privilege, under the New York statute, to have the testimony of physicians concerning information acquired in a professional capacity excluded.—Bauch v. Schultz, 109 Misc. (N. Y.) 548, 180 N. Y. Supp. 188.

Hospital Records as Evidence.—Clinical reports of a hospital were introduced in evidence without the person who made the entries being called as a witness. The senior surgeon, who signed them, testified that some of the facts stated in the reports were within his personal knowledge and others were not, and stated that "clinical records are not infallible by a long ways; they are frequently wrong, I will say." It was held that the trial judge did not err in instructing: "As to these hospital records, they have been received in evidence in this case. Their probative effect, that is, how much of them you believe, or how much of them you disbelieve, is left solely as a question for your determination."—Wilson v. Detroit United Ry., Michigan Supreme Court, 175 N. W. 172.

MANNER OF PRODUCTION OF OCULAR CONTUSIONS.

SEVERAL theories exist for explaining the lesion of commotion of the retina, but they do not apply to ocular contusion in general since the latter is really only a commotion of great amplitude produced by a greater physical force. Arit was the first to offer a theory of ocular contusion which was later accepted by Berlin and then modified and in that form maintained by Baeck. According to this theory the trauma produces a displacement of the ocular globe and a shock against the orbital contents on the side opposite the point of application of the force. At this point the wall of the globe is indented and then assumes its former position. An instantaneous compression of the choroid results and a vascular paralysis follows with a transudate of albumin from the blood into the retroretinal space with edema of the retina. The hemorrhage in the fundus oculi may be explained by this same theory: the globe is forced against the rigid optic nerve surrounded by its sheath which causes minute ruptures of the ocular membranes and vessels in the peripapillary region, hence the various hemorrhages in the fundus. This theory also explains the localization of traumatic hemorrhages, especially those taking place in the posterior pole of the eye.

The German school, headed by Denig and Lohmann, offered another theory of the pathogenesis of ocular contusion. The ocular shell becomes depressed at the point at which the traumatic force acts, resulting in a sudden hypertension of the vitreous with a contrecoup on the opposite pole of the eye. As thus presented, this theory is untenable, because the shock is not transmitted in a single direction by the liquid, but in all directions, and it can be rightly questioned why the posterior pole is alone involved. To overcome this objection the Germans maintain that, since the intraocular fluid does not vary, the envelopes of the eye are submitted to a sudden traction in an opposite direction in those portions near the point of the contusion. This traction is of necessity transmitted progressively to distant parts up to a diametrically opposite point where two equal inverse forces meet, and it is at this point that the ocular membranes are subjected to the greatest tension so that their dissociated elements offer a point of lesser resistance to compression by the vitreous suddenly hyperdistended. The compression results in vascular paralysis with an exudate and edema of the retina.

It is evident that this description of tissue tension is entirely theoretical because in reality, it is modified on account of the insertion of the envelopes of the globe to the papilla. Therefore, the maximum traction is often in the region of the papilla independently of the point of application of the trauma. If the macula is submitted to the greatest tension it will be the structure most involved, and this explains those cases of contusion with a marked decrease of central vision. This differs from Berlin's theory in that the Germans replace external compression by the contents of the orbit, by internal compression exercised by the vitreous on tissues previously weakened.

A third theory endeavors to explain more particularly the peripapillary ruptures of the choroid and the macular changes—two phenomena which are similarly produced. The eyeball is rotated by the trauma while the intraocular tension is not increased to any great extent. Immediately after, the rotation is arrested by the optic nerve so that the globe turns back in an inverse direction. As a result of this sudden movement rupture of the choroid ensues at the point of election, between the papilla and macula, where the choroid is attached to the scleral ring, on the more resistant and elastic portion of the choroid. This torsion produces the immediate changes occurring in the macula, quite independently of the blow and contrecoup which produce the edema of the retina. This explanation shows why the persisting traumatic changes occupy the central area of the fundus oculi so exclusively and it may possibly explain certain instances of post-traumatic atrophy of the optic nerve. Pechin assumes that the changes arising in the optic nerve are due to its elongation, the result of a traumatic luxation of the globe.

All these theories have their weak points because none of them is applicable to every case. The conditions under which the contusion occurs are so variable—the force of the trauma, its direction, its point of application, and its duration, that a single theory cannot possibly apply to each and every case. Possibly all of them are applicable in different cases.

ETIOLOGY AND SYMPTOMATOLOGY OF ARTERIOSCLEROSIS.

So far as the etiology of arteriosclerosis is concerned it is difficult to explain accurately the many causes that lead to this condition. Arteriosclerosis is really another term for the process of aging. In arteriosclerosis, the vascular system—the arterial portion of it in particular, as well as some other tissue cells are wearing out. While there are some factors which certainly and others which possibly hasten the aging process, in the majority of instances nothing is known of the exact manner in

which this is done. Dr. George William Norris writing on the subject in the *American Journal of the Medical Sciences* for July, 1920, says that among the factors which play an active part are (1) The wear and tear of life. (2) Infectious processes. (3) Intoxications. (4) Mechanical strain. As to the influence of heredity, it is obvious that while we know that heredity exerts a dominant influence in tending to long life it is quite as impossible to explain this influence as it is to explain the variations in growth and longevity in various species of animals. Why do some persons enjoy or rather have so great tenacity of life that they will undergo hardships, vicissitudes, physical strain, infectious disease, exogenous intoxications, and severe trauma, while others have so little vitality that they are incapable of withstanding rough usage of any kind?

After passing in review infectious diseases, intoxications and mechanical factors Norris considers those chemical factors, the internal secretions and protein metabolism, errors in which are regarded by some as the fons et origo of all human physical ills. While it is likely that arterial hypertension and vascular disease may result from disturbance of the internal secretions, it must be borne in mind that in the state of existing knowledge with regard to these secretory glands nothing very definite can be said. However, of all the secretory glands most is known concerning the thyroid gland and it is well established that the secretion of this gland exerts a marked influence upon the circulation, greatly increasing the work of the heart and the rate of blood flow and dilating the peripheral vessels. Sajous has suggested that an excessive protein diet acts through its effect upon the thyroid gland and has pointed out that many of the results of overeating resemble the symptoms of hyperthyroidism. There also appears to be an interrelation between the ovaries and other glands of internal secretion. Arterial hypertension is often first manifested at the time of the menopause. But as Norris remarks, these and many other thoughts along this line are suggestive and interesting, but largely speculative and not explanatory of the basic cause of arteriosclerosis. If endocrinology fails to solve the problem of arteriosclerosis, does another branch of chemistry, metabolic chemistry, promise more fruitful results? From the laboratory standpoint the answer is no, but clinically it seems established that overindulgence in food, especially protein food, has bad results.

As to the symptoms of arteriosclerosis they are almost too numerous to mention and, as Norris states, it is well to be sceptical regarding what appear to be purely functional derangements without demonstrable cause in individuals past middle life. Arteriosclerosis is a general disease, that is to say the chemical changes which cause vascular disease affect other tissue cells directly, just as they do the arterial walls, and therefore there is or should be a "presclerotic" stage. As in most pathological conditions the earliest stage is often impossible of recognition. Norris deprecates the use interchangeably of the terms arteriosclerosis and hypertension. The two conditions are often simultaneously present and prolonged hypertension frequently leads to arteriosclerosis, but that the reverse is true appears more than doubtful. In conclusion, Norris thinks that clinical arteriosclerosis may simply be an involutional process, a part and parcel of aging; or it may be mechanical or toxic in origin. Just how this involutional process is brought about we are not in a position to state. But it seems more than likely that it will ultimately be shown to be the result of chemical changes associated with the bodily metabolism, which exert their effects upon the individual visceral, vascular, and somatic cells either directly or through the mediation of the ductless glands.

THE ETHICS OF PRESCRIPTION WRITING.

IT is often said that prescribing is a lost art, and no doubt the chief reason why medical practitioners nowadays so seldom write prescriptions is because they do not know how to do so; they have never learned the art. While it may be true that many proprietary preparations are so skilfully devised and compounded that their effect is better than that of a written prescription, on the other hand many ready made formulas are used only because the physician is ignorant of how to write a prescription himself and is willing to rely on the statement of the manufacturer with regard to the therapeutic efficiency of the preparation. As Dr. James Burnet points out in the *Prescriber* for July, 1920, it certainly is a breach of the ethics of prescribing to recommend to a patient a preparation the action of the ingredients of which is not known to the prescriber, yet this is done almost every day. Another breach of ethical prescribing is the common one of merely telling the patient what to get. It is not only unethical but in a high degree dangerous to order drugs in this way. Of course, the druggist may be too careful to supply dangerous drugs when ordered in this slipshod fashion, but too frequently he is tempted to supply what is asked lest he lose his customer's patronage. Again it must be borne in mind that a slovenly prescription is never ethical.

According to Burnet to be strictly ethical a prescription should fulfill all the following essentials: (1) It should be carefully written on a properly prepared piece of paper or on a sheet of note paper, not on a scrap of anything that comes handy. (2) It should preferably be written in ink. (3) It should contain the name, and probably also the address of the patient for whom it is intended and should always be dated. (4) It should contain carefully worded directions for its use. (5) It should be initialed, or preferably signed, by the writer. (6) When it contains dangerous ingredients the words "not to be repeated" ought to be incorporated. (7) It should contain no incompatibility or proprietary remedy whose action is unknown to the prescriber. Burnet says that students too often

qualify without having had their attention drawn to these matters. The modern tendency is to discount prescription writing altogether and to store the mind with pharmacological actions, most of which have not been put to any real clinical test, and consequently are of comparatively little value from the point of view of the actual practice of medicine. The author deprecates the present tendency to ignore the practical side in teaching and remarks that the student of to-day will be the practising doctor of to-morrow, but one would rather think from the instruction given him that he was intended to be a research student in a laboratory to the end of his days.

Acute Myoclonic Encephalitis and the Electric Chorea of Dubini.

Litvak of Paris contributes an article with this title in *La Riforma Medica* for March 27, 1920, xxxvi, 13. In 1846 a modest practitioner of the Milan Hospital, Dubini published a monograph on "electric chorea," his study having been presented before the Congress of Scientists at Naples. The affection was apparently a new one and limited to Lombardy. The term "electric chorea" was devised to characterize the motor phenomena, which were of the sort seen in the ordinary or Sydenham chorea but resembling the contractions produced by the electric current. The muscular behavior was constant and pathognomonic. Next he mentions other symptoms as headache and pain in the nucha and spine. Other phenomena were fever, sopor, stupor or delirium, muscular rigidity, and other more or less vague symptoms. In these cases general convulsions usually developed and led to coma. The disease was so grave that of 38 patients but 2 recovered. Nothing characteristic was found at autopsy. Trua, a colleague of Dubini, later made the discovery that stupor was not a mere complication but an integral part of the disease. Another colleague, Pignacca, noted four cardinal symptoms—the muscular shocks, muscular contractions, epileptiform attacks, and cephalic symptoms, including headache and somnolence. Half a dozen other Italians and a number of foreign physicians discussed the disease—the latter apparently only from the Italian descriptions. According to a recent study, cases of Dubini's disease were reported for about twenty years after his original description. The present author, however, shows that the condition was seen long after that period, for in 1884 Grocco wrote a monograph on it which included his personal cases. He was probably the first to grasp the infectious nature of the malady. He fixed the seat of the process in the brain and cord. Despite some want of agreement the similarity between this affection and the myoclonic encephalitis of to-day may possibly point to one and the same affection.

An Epidemic of Alopecia.

Captain Rutherford, a British Army surgeon, contributes to the columns of *La Presse Médicale* for April 28, 1920, xxviii, 26, an account of an alleged epidemic incidence of alopecia in association with the Teutonic retreat of 1918. During the progress of the latter the alien army took with them all of the potatoes, farm animals, and the thrashed wheat, while the unthrashed wheat was burned. Other articles taken along comprised the linen, while the mattresses were slit in pieces, perhaps in the hope of finding concealed money. Many of the inhabitants were driven into Belgium and Holland, and as far as possible the whole area was inundated and otherwise devastated. The results may be imagined, for at a stroke the inhabitants were deprived of food, shelter, fuel, and means of transport. Certain maladies sprang into existence, among the first being influenza associated in part with overcrowding among the refugees. Next is mentioned scabies and a tetter-like eruption. In the aged there developed cardiac weakness and edema, while nephritis subjects promptly developed uremia, probably from the chilling of the surface. Under favorable circumstances this type of nephritic might have lived in relative health and usefulness for years. The author personally in his official capacity treated over 12,000 of these subjects for various ailments over a period of five months, but a complete analysis of the material is not attempted in this connection. The balance of the article is devoted to an account of alopecia which took the form of a defluvium—a simple shedding of the hair. This was seen in between 2 and 3 per cent. of those under treatment. The loss did not occur at the acme of the physiological misery but after the reaction to better conditions. The author is inclined to look upon it rather as a reflex of four years of tension of war conditions than to the final acts of the enemy. At any rate, the loss followed the armistice and the condition continued to develop for some months later or up to March, 1919. There were but few cases of baldness of special types, as alopecia areata and alopecia from seborrhea, and in the vast majority of these cases the condition must be regarded as symptomatic of the general state.

Fixation Abscess in the Treatment of Bubonic Plague.

An abstract in the *Office International d'Hygiène Publique* for March, 1920, xii, 3, from the Bulletin of the French Medico-Chirurgical Society of West Africa describes the treatment of 256 cases of bubonic plague with fixation abscess. The authors are Foulon and Forgues and the locality is Saint Louis, Senegal. The mortality was about 36 per cent., which was asserted to show an improvement over that accompanying the ordinary methods in use. Turpentine was used to excite the abscess, 3 c.c. being injected under the skin of the arm or leg, the seat of the buboes. The treatment must be instituted early and the abscess opened early, else phagedena may develop. The procedure is believed to lessen the chance of the pulmonary involvement and to favor the abortive course of the primary bubo and thereby alleviate the exquisite tenderness of the latter. The germ of the idea is found in the discovery by Arthaud that in ulcerated buboes pulmonary complications are much less likely to occur. Plague subjects with ulcerations almost never die with secondary pneumonia and resist toxemia better. Further, subjects with indigenous phagedenic

ulcer who contract bubonic plague seem always to recover. Again, as far back as 1918 it was noted that in accidental suppurations following hypodermic injections of a certain medicament (known as septacrol) the abscess formation had salutary results. In a discussion which followed, the fact was brought out that for Senegal the mortality in untreated cases in the late epidemic was not over 40 to 45 per cent., which tends to throw doubt on the value of the author's method, since the mortality in his cases was 35 per cent.

Psychopathic Degeneration and Disequilibrium.

The subject of the half responsible is discussed by Babonneix and Brissot in a recent number of the *Revue neurologique*, abstracted in the *Journal de médecine et de chirurgie pratiques* for April 10, 1920, xci, 7, with special reference to military life. First to note is dissociation of mental powers, some of these being weak or rudimentary, while the others are normal or excessively developed. Quick intelligence is seen side by side with instability or perhaps complete lack of affectivity involving absence of sympathy for others. Next to these dissociations should be noted lack of adaptation to environment. There is no self-discipline, hence no response to discipline from others. The subject is antisocial and in military life insubordinate. The third feature is impulsivity, the subject acting quickly and without any attempt to count the cost. Some acts may seem to have no motivation at all. Peculiar personalities are seen, one of which is the mythomaniac or habitual liar. Fervor and passion for some hobby are common, the subject going in heart and soul for some activity—hence there were many would-be aviators of this type. One of the most common is the passion for inventing something and the impractical inventor who neglects all other activities is apt to be of this type. The disequilibrated subject is never a debile or weak-minded man, but his balance is upset. In fixing responsibility for crime, etc., the authors would be guided in part by the presence or absence of physical stigmata—craniofacial asymmetry, ogival palate, and anesthesia of the pharynx and conjunctiva.

Sterility of Masculine Origin.

Deluca and Widakowich of Buenos Aires contribute an article on this subject to the *Revue française de gynécologie* for February, 1920, xv, 2. It is a grievous technical error, they hold, to subject a woman to dilatation of the cervix and other interventions when the trouble may be with the husband; to say nothing of the false position in which she is placed with its accusations and recriminations. Hitherto data have been lacking on this subject in Argentina and this first contribution is but a modest one. The male alone has been studied in this connection and the authors have found that one man in ten is an azoospermic, a percentage which agrees well with that of other countries furnishing large statistics. Richet has claimed that this ratio is biological and universal, uninfluenced by climate or diet. But this does not accord with the fact that in the author's material every azoospermic had suffered from gonorrheal epididymitis. Perhaps Richet's 10 per cent. is merely an expression of the frequency of gonorrhea, but this malady has not the same incidence in all localities. Male responsibility for female sterility is of course twofold. First, the man may be rendered azoospermic by this disease and hence unable to procreate. Secondly, and much more frequently, he may retain his own power of procreation, but infect his wife after marriage, with resulting tubal sterility. If we consider both components jointly, the man, or the disease gonorrhea, is responsible for more than two-thirds of all the sterile unions, the percentage in some figures reaching as high as 70.

News of the Week.

Survey of Industrial Cripples in Ohio.—The Industrial Commission of Ohio has made application to the federal government for its share of the appropriation provided by the Fess Bill to create commissions to make a survey of the physically handicapped. Ohio, so far as is known, is the first State to apply for a part of this appropriation, and will be the first to undertake an extensive survey of its industrial cripples. According to the *Ohio State Medical Journal*, the contemplated survey will be very similar to a survey of crippled children which is being initiated by the Ohio State Medical Association in cooperation with the Ohio Institute of Public Efficiency, the State Department of Health, the Board of State Charities, the State Department of Public Instruction and the Ohio Society for Cripples which has been organized by Ohio Rotary Clubs.

Defective School Children.—Of the thirty-five thousand pupils in the schools of Cleveland, Ohio, one-third are physically defective, according to the findings of a city health and hospital survey by Dr. R. P. Emerson, professor of children's diseases in Tufts Medical School, Boston. Improper feeding, over-fatigue, and lack of home control are some of the factors which contribute to this physical unfitness.

Trachoma in Ohio.—Thirty-four children from public and parochial schools of Columbus, Ohio, and a number from other towns in that State, have been operated on for trachoma as the result of a survey of school children in the towns concerned by the United States Public Health Service and the State Department of Health.

Housing and Health.—In the opinion of Health Commissioner Royal S. Copeland the housing situation in New York City is such that unless action is taken immediately public health and public morals will suffer immeasurably.

"Kissing Bee" Ended in "Vaccination Scramble."—A party of "sub-debs" in the town of Lewes, Del., was attended by a seventeen-year-old Lothario from Dover. Various kissing games were staged in honor of the visitor. The next day he was sent to the isolation hospital, whereupon there was a general rush to doctors to be vaccinated on the part of the other participants in the "kissing bee."

Popular Prohibition Beverages.—From the Washington City superintendent of police comes the statement that toilet water and hair tonics are

growing in popularity in that city as beverages. The statement is based on statistics collected during the past six months. During that period there were 543 whiskey drunks and 225 alcohol; then came the tipplers of flavoring extract, numbering 142; hair tonic, 1,033; bay rum, 153, and toilet water 33.

Forty-three-Day Fast.—A negro bandit died in the Schuylkill (Pa.) prison on August 11 after fasting for forty-three days. This fast exceeded by three days that of Dr. Tanner, who broke the fasting record a number of years ago.

Smallpox on Steamship.—The British steamship *Princess May*, which arrived at New York from Port Antonio, Jamaica, a few days ago, with forty-three passengers, all negroes, brought an additional case of smallpox to the number already being treated here. The patient was sent to Swinburne Island; the rest of the passengers were sent to Hoffman Island for observation.

Compulsory Physical Training at McGill University.—With the installation of complete gymnasium equipment of the most modern type, beginning next year each student of the first two classes will be compelled to undergo at least two hours' physical training weekly. This may be in the gymnasium or on the track and in the field.

Secrecy on Part of Physician Not Obligatory in Case of Communicable Disease.—A guest in a small hotel in a small town in Nebraska consulted a physician, who found the patient to be suffering from a communicable disease (presumably venereal in character). Being medical adviser to the family who ran the hotel, the physican warned the landlady as to the nature of the guest's affliction, and instructed her in measures to guard against contracting the disease while caring for the room. The landlady ordered the guest to vacate, whereupon he brought an action against the physician for damages for "alleged breach of duty arising from confidential relationship between defendant, who is a physician, and plaintiff, who was his patient." The Nebraska Supreme Court directed a verdict in favor of the defendant, holding that a physician is not compelled to maintain secrecy in the case of communicable disease when the health of other persons is endangered.

Dr. Archibald Keightley, a former practitioner in New York, who has resided in London for a number of years, has returned to this city, where he will shortly resume practice, paying special attention, as previously in London, to the disorders of nutrition and those dependent upon defective metabolism. His temporary address is care of the editor of the MEDICAL RECORD.

Dr. L. Duncan Bulkley announces his retirement from active practice. He will in future devote his attention to a consultation practice in dermatology and the treatment of malignant disease.

Dr. Dunning S. Wilson has accepted an appointment as director of the medical department of the French Lick Springs Hotel, French Lick, Ind. Dr. Wilson served in the Medical Department, U. S. A., on the Mexican Border and later with the A. E. F., receiving while there a citation from General Pershing, and being retired at the close of the war with the rank of lieutenant-colonel.

The Bubonic Plague.—A press dispatch from Paris dated August 14 states that four cases of plague have been discovered in that city, but adds that no apprehension is felt as the Pasteur Institute serum has been found to be curative in 93 per cent of the cases in which it has been tried.

According to the Mexico correspondent of the New York *Tribune*, the plague outbreak in Vera Cruz has been overcome through the efforts of Dr. Carl Michel of the U. S. Public Health Service, who was sent unofficially to that city some time ago. By the exercise of tact and diplomacy he overcame the prejudice of the local health officials and caused their cooperation in instituting an antirat campaign, as a result of which the threatened epidemic was averted.

More Typhus in Mexico.—Forty-eight cases of typhus fever have been reported in San Pedro de las Colonias, State of Coahuila, Mexico. The town had been without water for forty-eight hours, according to advices under date of August 8.

Sedative Action of Sugar.—Following the recent riots at the State Reformatory for Women, Bedford, N. Y., Acting Superintendent Mrs. Frank L. Christian, has been testing the peace-making qualities of sugar. With the increased allowance of sugar and enlarged portions of food, the plan "to stuff them to stupor and sweeten them to "peace" seems to offer a prospect of success.

Medical Society Elections.—THE CHATTAHOOCHEE VALLEY MEDICAL AND SURGICAL ASSOCIATION, at its twentieth annual session held at Warm Springs, Ga., July 13 and 14, the following officers were elected for the ensuing year: *President*, Dr. William C. Gewin, Birmingham, Ala.; *Vice-President*, Dr. Thomas Neal Kitchens, Warm Springs, Ga.; *Secretary-Treasurer*, Dr. William J. Love, Opelika, Ala.

Charitable Bequests.—By the terms of the will of the late Watman Haas of New York City, Mt. Sinai Hospital and Mt. Sinai Training School for Nurses will receive $10,000 each. Other provisions were made as follows: $5,000 each will go to Mt. Sinai Hospital, Montefiore Home, United Hebrew Charities, Young Women's Hebrew Association. Hebrew Benevolent and Orphan Asylum, Hebrew Sheltering Guardian Society, Hebrew Technical Institute, Home for Aged and Infirmed Hebrews, Educational Alliance, Jewish Protectory and Aid Society and Crippled Children East Side Free School, and of $2,500 each to Mt. Sinai Pension Fund, St. Vincent's Hospital, Presbyterian Hospital, Hebrew Technical School for Girls, Beth Israel Hospital, and Home for Hebrew Infants.

Samuel Haas of New York City, who died last May, left $5,000 to Mt. Sinai Hospital, $2,500 to Montefiore Home, and $1,000 to the Hebrew Benevolent Orphan Asylum.

The suit to break the will of Charles W. Fairbanks, who died in Indianapolis, Ind., in 1918, has been decided adversely, and the will stands. By its provisions the following bequests are made: The Methodist Hospital of Indianapolis gets $50,000, Ohio Wesleyan University at Delaware, Ohio, $25,000; Depauw University at Greencastle, $25,000, and St. Vincent's Hospital, Indianapolis, $2,500.

Exhibit of Work of Crippled Children.—Articles made by the crippled children of the Bakule school in Prague, Czecho-Slovakia, are on exhibition at the

Horace Mann School, Columbia University. The Bakule school is fostered by the Junior Red Cross of America.

Neglect of Vital Statistics.—According to the Children's Bureau of the Department of Labor, twenty-five of the forty-eight states, or more than half, fail to keep satisfactory records of the population. The department urges that more attention be paid to vital statistics.

Tribute at Bier of General Gorgas.—When the body of the late Major-General William C. Gorgas arrived at the port of New York on the United States Army transport *Pochahontas*, August 11, a salute of thirteen guns boomed as the ship passed Governor's Island. The body was removed in a hearse to the ferryboat Elmira, by which it was conveyed to New York. It was preceded by a detail of 100 men of the Thirteenth Infantry and followed by automobiles conveying Mrs. Gorgas and others of the escort. The body lay in state for two hours in the mortuary of the Pennsylvania station, where many representatives of civic, patriotic and other organizations paid honor to the great scientist. Upon the arrival of the body in Washington it was escorted to the parish house of the Church of the Epiphany by two troops of cavalry. Brief services were held for members of the immediate family. The body lay in state until Monday, August 16, when it was buried with military honors in Arlington National Cemetery.

Obituary Notes.—Dr. STANLEY DAVIS TERRY of New York City died August 7. He was seventy-five years old and wsa a graduate of the College of Physicians and Surgeons, New York, in 1875.

Dr. HENRY E. MERENESS of Albany, N. Y., died August 5 at the age of seventy-one. He was graduated from Albany Medical College in 1874.

Dr. WILLIAM J. KARLSLOE, a retired physician of New York City, died at the Post-Graduate Hospital August 8, at the age of sixty-nine. He was graduated from Louisville University Medical Department in 1893. Dr. Karlsloe was born in Sweden but came to this country in early life.

Dr. SHERMAN COOPER, a retired physician who had practised for sixty years at Westfield, N. J., died August 8 in New York City, at the age of eighty-eight. He was graduated from New York Medical College in 1857, and served as surgeon during the Civil War.

Dr. OLGA DAVIS, known as the "Good Angel of Chicago's Ghetto," died August 10 at Mackinaw Island where she had gone to recuperate after a serious operation. She was graduated from the University of Illinois College of Medicine in 1909.

Dr. ROBERT A. ROBINSON of Jamaica, L. I., died August 11.

Dr. WILLIAM M. HANDLEMAN of New York City died August 8, at the age of thirty. He wsa graduated from Long Island College Hospital in 1911. He was a member of the Bronx County Medical Society.

Dr. EMIL HEUEL of New York City died August 11 at the age of fifty-eight. He was graduated from New York University Medical College in 1883, specializing in otolarynology. He was visiting surgeon to St. Luke's and the Polyclinic Hospital, and was a member of the American Medical Association and other bodies.

Dr. WILLIAM FRANCIS GODWIN died at his home in Englewood, N. J., August 11, at the age of eighty.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 23, 1920.

Health of London.—Dr. W. H. Hamer, the medical officer of the London County Council, has issued recently his report for the year 1919. The outstanding feature of the report is that in the closing weeks of the year the births exceeded any previous figures, and the increase has been maintained during 1920. More marriages took place in London last year than in any previous year, with the exception of 1915. There was considerably less mortality among the civil population, and the death rate among infants under one year of age was the lowest on record. The figures of the births, marriages and deaths for 1919 and 1918 are as follows:

	1919	1918
Births	82,525	70,796
Marriages	50,222	42,893
Deaths	59,114	75,928

In an introduction to the report Dr. Hamer draws attention to some salient facts, among these being that the year 1919 was one of exceptionally low mortality, although there was much increase in the number of deaths from influenza and allied causes in the first quarter. Save for two weeks of cold and inclement weather during February, the conditions were favorable to health. The report pionts out that the population of the County of London at the census of April 3, 1911, was 4,521,685, and it was estimated by the Registrar-General to have declined to 4,518,021 in the middle of 1914. The births during 1919 numbered 82,525, as compared with 70,796 in 1918, and a yearly average of 110,951 during the pre-war period 1911-14. The Registrar-General estimates the birthrate at 18.2 per 1,000 of the total population. The movement of the birthrate during the year was remarkable, for while in the first quarter the births were lower than in any quarter since the beginning of the war, in the closing weeks of 1919 births were being registered at a rate in excess of all previous records. The actual number of births registered in London increased continuously up to the commencement of the eighties, and remained practically constant until about 1900; the annual average during this period was some 132,500. By 1911 the figure had fallen to about 110,000, and this number was maintained up to the time of the war. The increase in marriages, in conjunction with the decline in the outward movement of the population served to arrest the decline in total births. Had the war not intervened these factors might probably have operated to keep the births at about this level during recent years. On this assumption the loss in births caused by the war up to the end of 1919 would have amounted to 114,496. The deaths among the civil population during 1919 numbered 59,114, as compared with 75,928 in 1918. The Registrar-General gives the deathrate as 13.6, the corresponding rates in years back to 1916 being 19.2, 15.7, and 14.6. The deathrate among infants under one year of age was 85 per 1,000 births, a rate below any hitherto recorded in London, the lowest rate previously having been 91 per 1,000 births in 1912. As for in-

fectious diseases, the summarized particulars are as follows: During the year 1919, 26 cases of smallpox were notified, four of which proved fatal. There were 342 cases of typhoid fever, as compared with 357 in 1918. The deaths numbered 63, against 82 in 1918. There was a substantial reduction in the notification of measles, the figures for the year being 29,112, as compared with 45,115 in 1918. Deaths, too, were far less, being 359, in contrast to 1,651. The mortality was only 0.08 per 1,000, this being a great deal below any rate hitherto recorded even when the diminution in birthrate has been fully taken into account. Scarlet fever, however, showed a big increase, the figures being 12,935 for 1919 and 6,807 in 1918. The deaths numbered 147. The number of cases of diphtheria notified was 9,459 as compared with 8,173 in 1918, and the deaths 775, or 106 more than the previous year. Deaths from pulmonary tuberculosis in the civil population during 1919 numbered 5,332, a decrease of 1,716 from the previous year. Tuberculosis other than phthisis caused 992 deaths in 1919 as against 1,575 in 1917 and 1,398 in 1918. The number of primary cases of tuberculosis notified in London during 1919 was 15,587, against 19,178 for 1918. Reference is made in the report to cases of anthrax which occurred in London during 1918 and which was commented on in a previous letter. In 1919 11 cases of anthrax were notified in London, three of which proved fatal. Seven were directly attributable to the patient's employment and four to infection from shaving brushes. The brushes which were responsible for cases of anthrax in London, as well as in other parts of the country, were covered by a certificate issued by the Japanese Government to the effect that they had been properly disinfected. It is remarked in the report that in view of the widespread distribution of the Japanese brushes, the extension of the disease in Ireland was not to be wondered at, and had it not been for the stringent methods adopted by the health authorities it is probable that the outbreak would have assumed larger dimensions. Dr. Hamer, dealing with the question of the treatment of tuberculosis under the National Health Insurance Acts, states that in the area of the County of London there are 33 dispensaries, of which 11 are provided by the central fund, two by other voluntary committees, 11 at hospitals, and 9 by municipal authorities. In addition, the Council has 685 beds for children and 275 beds for adults. The number of patients treated in institutions during 1919 were 192 men, 635 women, 616 boys and 609 girls. There were also 976 children dealt with in cooperation with the Invalid Children's Aid Association and 365 by other means. In the report particulars are given of the progress of the scheme for the diagnosis and treatment of venereal disease which, as a result of the Regulations issued in July, 1916, came into operation on Jan. 1, 1917. The number of beds available in hospitals for the use of in-patients is at present 211. The following table shows the extent to which the facilities have been utilized by London patients during the three years the scheme has been in operation:

	1917	1918	1919
Number of hospitals	22	25	26
New patients	12,211	12,538	20,908
Attendances	96,398	131,869	232,659
In-patient days of treatment	48,860	49,590	54,431
Pathological examinations for practitioners	2,992	5,122	8,258
Practitioners on the approved list	108	178	240

Dr. Hamer gives a detailed account of the results of medical inspection of school children. In a general survey of the work, from the points of view of the effects of dirt, overcrowding, and hunger, conditions especially liable to undergo aggravation during and directly after a war, the improvement noted has been good beyond expectation. At the same time, 83,007 children in the elementary schools were found during the war to require treatment for one or more defects.

Speech by the Minister of Health in the House of Commons.—Dr. Addison, the Minister of Health, made a very important speech on July 15 in the House of Commons on the work and future work of his department. With regard to the question of the prevention of disease, Dr. Addison said it must be borne in mind that the Department came into being during the armistice, when half Europe was devastated by plague and other scourges, and when the first thing to be done was to secure this country against infection. It was necessary to organize a sanitary cordon round the land, and this duty had been discharged with remarkable success. Missions were sent to Poland, where typhus was ravaging the country, and to other parts of the world, and up to the present none of the scourges prevailing elsewhere had afflicted the people of Great Britain. Last year another invasion of influenza was feared, and as in the previous year 37,000 people, mainly adults, had died, it would be seen that the visitation was as terrible as anything of the kind the country had experienced for hundreds of years. A group of experts was organized and sat constantly in session, devising means for warding off the danger. Protective vaccine was distributed and freely used by large numbers of people, and though offense was given to opponents of this method of treatment, the results justified the means. The country escaped the epidemic. New measures were also being taken in the treatment of tuberculous diseases, in view of the fact that large numbers of patients after leaving the sanatoria break down again, to their great disappointment and sorrow, and the loss of public money. Village colonies composed of persons affected had been established. The communities worked at trade union rate of wages, and were largely, though not altogether self-supporting. Referring to matters affecting mothers and children, he said that more than 700 women were being prepared under training schemes for service as midwives. He had a startling figure to disclose, showing the improvement which had taken place recently in the infant deathrate. Towards the end of last century and at the beginning of this the rate was practically stationary at about 150. It began to fall in 1906, when it was 132; in 1918 it was 97, and last year 89. For the last three quarters of last year and for the first quarter of this the figure was only 78, about half what it was twenty years ago. Turning to the position of the voluntary hospitals and their assistance by the Ministry, Dr.

Addison said they had under the Poor Law hospitals containing more than half the hospital beds of the country. He had arranged to have these surveyed from the medical point of view and also so that they might be aware of the financial side. The position of the voluntary hospitals had been brought to his attention on many occasions, and meetings had taken place with those responsible for their direction. For the present, the King Edward Fund, in consultation with the Ministry, had put aside a quarter of a million ($1,250,000) for the relief of the immediate necessities of the hospitals and grants from that sum were now being made. Other proposals were being worked out. Those who represented the voluntary hospitals, and who came to the Ministry to discuss the matter seemed to have had the idea in their heads that the Ministry was greedy to take hold of these institutions for some purpose of its own. The Ministry had enough to do, and had long lost any intention of being greedy in that way. Many of these institutions were the pioneers of the world in their efficient service, and it would be a mistake of the first order to seek to interfere with that efficiency. Any scheme that the Ministry put forward would be designed to promote their public utility and to help them. In another matter the Ministry had also taken an essential step. They were doing what they could to secure that further provision should be made for scientific and medical research, and the Treasury had made a grant for the services of medical research of £125,000 as compared with the figure of less than £60,000 previously arranged. In no direction was expenditure more justified, and he would give one or two illustrations. A grant was made from that source with regard to T. N. T. poisoning, for which they were paying several thousand pounds per week compensation. They gave a few hundred pounds out of the research fund, with the result that T. N. T. poisoning had been practically abolished. As the result of another of the grants made out of the fund, work was done in the Eastern Command in connection with heart cases, resulting in that command alone, in a saving of £50,000 in one year. During the war various grants were made in connection with typhoid. In the South African War the total strength of the British Army was about 580,000, and the ration strength 208,000. There were 67,684 cases of typhoid and 8,022 deaths. During the recent war the total strength of the British forces at a low estimate was 5,000,000, with a ration strength of 1,200,000. The men were living under miserable conditions in muddy trenches, and had the number of typhoid cases been in the same ratio as during the South African War there would have been 400,000 cases and 56,000 deaths. But research work had gone on, and the actual result was that throughout the whole war in the British forces there were only 7,423 cases of typhoid and 266 deaths. There could be no greater justification for expenditure on intelligently directed research.

Cancer Mortality in Great Britain.—According to the Registrar-General's Report for 1918, cancer mortality, if stated in the form of an ordinary crude death-rate, was higher in 1918 than in any other year, but if comparison be made by means of standard rates which allow for the present abnormal age constitution of the male civilian population, there will be seen to have been an appreciable decrease from the previous year's record. Standardization fails to eliminate entirely the fictitious increase due to the exclusion from the population in war years of a large number of men furnishing very few deaths from cancer. An attempt at a fuller correction on this account shows that the standardized cancer mortality of 1918 was probably lower than that of 1911-14 also.

Menace of Typhus in Eastern Europe.—In a Chadwick Lecture on "Health Conditions in Eastern Europe," delivered at the Surveyor's Institution, Westminster, on July 15 last, Dr. Norman White of the Ministry of Health, who is a member of the League of Nations Typhus Commission, laid stress on the serious menace to the West of Europe caused by the prevalence of virulent disease in the countries on the western borders of Soviet Russia. Dr. White said that the sanitary conditions there were deplorable enough before the war. Since 1914 they had grown steadily worse. In 1917 the death-rate exceeded the birth-rate in every town and village of Poland. A virulent epidemic of typhus still prevailed especially in Galicia. Soap, fuel and changes of clothing were unobtainable in many parts; the poorer classes were almost universally infested with lice, which carried the disease from the sick to the healthy, and privation had lowered the resistance of the population to infection. Overcrowding was rife; 325,000 houses had been destroyed in Poland during the war and 438,000 in Galicia, and there was a continuous stream of refugees across the border from Russia, many infected with typhus, nearly all infested with vermin, and most of them clothed in rags, which fell in pieces on any attempt to disinfect them. Dr. White quoted the experience of Holland in 1918-1919 as an illustration of the danger to the rest of Europe of the focus of epidemic disease, which further was an important factor in the promotion of social and industrial unrest, and declared that unless generous help was forthcoming quickly from outside, the situation would get entirely beyond control.

In an annotation in the *Lancet* July 17, 1920, this subject is referred and attention is directed to the splendid work done and being done by members of the Medical Corps, U. S. Army, in Poland, sent by the President under the command of Colonel Harry L. Gilchrist and known as the American Typhus Fever Expedition. Colonel Gilchrist, in a report contained in the *Military Surgeon* for June last, sums up the needs of Poland as follows: Soap in thousands of tons, hospital linen and undercloth-ing in hundreds of thousands of sets, hospital equipment for thousands and thousands of beds; and declares that if unless checked "this epidemic will threaten the whole of Europe." There is no doubt that Poland's need is extreme and will appeal with special emphasis to Americans because their medical men have solved the problem of the means whereby typhus is spread, and have interested themselves in the ills of this sorely stricken country.

Laboratory Transmission of Sleeping Sickness.—Levaditi and Harvier succeeded in transmitting encephalitis lethargica to rabbits and monkeys by inoculating portions of the cerebellar peduncles of human being dead of the disease. The cause is evidently a filtrable virus.—*Le Progrès Médical.*

3. Observations upon Ductless Gland Therapy.—Charles H. Lawrence emphasizes the fact that the symptoms of the early stages of disordered endocrine function are at present often overlooked because they are not well understood. Though the symptoms of such conditions are often polyglandular in character, there exists a "characteristic and recognizable syndrome for a primary derangement of each individual gland." The recognition of the syndrome is essential for intelligent glandular therapy. These syndromes are briefly described by the author.

4. Observations upon Various Types of Diabetics under the Present Method of Treatment.—F. Gorham Brigham, from a study of a large number of diabetics over a period of ten years, draws the following conclusions: 1. That by all the modern methods of low calory diet the diabetic patients do better than by former methods. 2. That without careful blood estimations diabetics cannot be satisfactorily treated and good results obtained. 3. That the complications of diabetes will develop even though the urine contains no sugar if the blood figures remain high. 4. That the prevention of obesity will reduce the number of diabetics tremendously. 5. That the study of other functions, such as kidney function, and the removal of all possible foci of infection, are essential to having the diabetic patient do well. 6. That the routine twenty-four-hour urines must be more frequently done, or routinely done, to be able to recognize diabetes as well as other kidney conditions early, and allow earlier treatment. 7. That the disease diabetes illustrates the importance of laboratories where simple routine analyses can be done at a reasonable figure.

6. Intravenous and Intraspinous Treatment of Meningococcus Meningitis.—David Goldblatt holds that intravenous therapy, combined with intraspinous treatment, aims at a rapid sterilization of the blood and the meninges, and thus shortens the period of morbidity. It reduces the required number of intraspinous treatments, and if started early may abort the disease. With a moderate amount of care the intravenous therapy is free from danger should be used in cases that clinically indicate a severe type of the disease.

3. Suppression of Urine in Pregnancy and the Puerperium.—Robert Jardine and Alex. Mills Kennedy, working on behalf of the Medical Research Council (Great Britain), report eleven cases of suppression of urine in pregnancy and the puerperium. In each case the patient suffered from what is known as the toxemia of pregnancy. The cause, they hold, seems to lie in the action of a toxin, and if there is chronic interstitial nephritis present there is grave risk of suppression of urine. When suppression of urine is fairly established treatment by medicines, transfusion, etc., seems hopeless. Decapsulation of the kidneys in cortical necrosis has done no good, and one cannot see how it can be of any use. In a case of nephritis it might do some good. In one such case some urine was secreted, and the patient lived longer after the operation than any of the cases of necrosis operated upon, but the result was the same. It is impossible to differentiate between cortical necrosis and chronic nephritis, and it is quite apparent that the two may coexist. A history of a previous nephritis would argue against necrosis. The only hope is in prevention, by the careful early treatment of toxemia of pregnancy. Of the eleven cases reported, pathological reports on the condition of the kidneys are available in eight instances, the findings in which are given. Successful treatment will depend upon the earlier recognition of the toxemic state and the application of such remedies as will eliminate or counteract the toxin before it has caused necrosis of the tissues or vascular thrombosis.

4. Hemorrhage Following the Operative Treatment of Internal Hemorrhoids.—W. B. Gabriel bases this contribution on an analysis of 500 cases of internal hemorrhoids operated upon at St. Mark's Hospital for Diseases of the Rectum (London) in the course of the last sixteen months. Ligature was performed in 470 cases, including 62 cases in which ligature was combined with treatment for a fissure or fistula. The clamp and cautery method accounted for 18, and Whitehead's operation for 12 cases. It was found that severe

secondary hemorrhage following a ligature operation for internal hemorrhoids is a possible complication, occurring in this series at the rate of just over 1 per cent. of cases—5 in 470. The rectum necessarily becomes a septic area when the bowels are opened three days after operation, and it is difficult to see how the risk of a secondary hemorrhage from sepsis can be further eliminated. The average date for the hemorrhage is seven days after operation. It usually follows an action of the bowels, hence in the postoperative treatment the prevention of constipation is of the greatest importance in minimizing the risk of trauma. The bleeding tends to be concealed, and a suspected case of hemorrhage should be investigated, without delay, with a tubular speculum. Plugging the rectum with a vulcanite or rubber tube is the most generally efficient method of controlling the hemorrhage, which is to be combined with suitable general treatment.

3. Open Ether, Without Chill. Lionel Jas. Picton.

2. An Operation for the Radical Cure of Inguinal and Femoral Hernia.—Sir G. Lenthal Cheatle, from the experience gained in operating recently upon eight cases for the radical cure of inguinal hernia at King's College Hospital, evolved an operation, the essential features of which are as follows: The patient is placed in the Trendelenburg position, an incision is made to one side of the middle line, the rectus abdominis is split longitudinally, and the abdominal wall is retracted to the side of the operation. The peritoneum is smoothed away by a dry swab from the parietes. The operation is conducted without opening the peritoneum. The sac between the internal ring and the surface of the peritoneum is delimited by insinuating the forefinger between it and the external iliac artery and vein. The sac is ligated at the peritoneal surface. The part of the sac that extends into the inguinal canal is pulled up into the subperitoneal space as far as it will come, tied as low down as possible, and then it is allowed to slip back (or is replaced) into the inguinal canal; so that it cannot act as a guide for a recurrent hernia.

3. The Genesis and Meaning of Tics (*Continued*). H. Laveson.
4. Anesthetic Notes. Arthur E. Guedel.

1. Some Points on the Diagnosis and Treatment of Goiter.—John F. Barnhill states that objectively there are at least three types of goiter: (1) A type that may very properly be called physiologic goiter. This occurs chiefly in girls during puberty, and in pregnant women, and may disappear spontaneously when sex development is complete, or when confinement has taken place. (2) That which is large, clearly observable, and often of such size as to greatly deform the patient's neck. (3) That which may be comparatively small, even so small as to attract no attention from the physician, and therefore may be overlooked as the real cause of a serious and often fatal malady. The larger the goiter usually the fewer and less distressing are the symptoms, and the less danger to life. Conversely, the smaller the goiter within certain limits the greater the number of severe symptoms and the greater the danger to life. Since it is now well proved that the thyroid when diseased may throw into the system a toxic secretion which will set up serious heart and nerve disturbances, it becomes an essential in the examination of all such cases to examine most critically the thyroid gland when these symptoms are present, and to endeavor by the use of every diagnostic aid to correct or eliminate the thyroid as a causative factor. Failure correctly to diagnose toxic goiter will seldom occur if the following points are observed: (1) Always examine the neck for thyroid enlargement and pulsation in all cases of nervousness, sleeplessness, sweating, extreme weakness, and especially of rapid heart action. (2) Especially should the thyroid be investigated if in the presence of the above symptoms, or even some of them, there should be a history of exhaustion on slight exercise and of loss of weight. (3) Toxic thyroid disease runs its course almost without exception with no rise in temperature. The absence of fever in cases with rapid heart, sweating and loss of weight justifies a thorough investigation of the thyroid gland. (4) Employment of laboratory tests. The treatment of goiter depends upon the type, and stage of progress. Nearly all goiters may at first be considered medical cases. When not cured by medical and hygienic measures, they then fall into one of two classes, namely, those wholly surgical, and those both medical and surgical. All large cystic and colloidal goiters are wholly surgical. Probably all cases of thyrotoxic goiter are both medical and surgical. The writer presents eight cases representing the different types and their treatment.

6. Diagnosis of Early Gall Bladder Disease.—Russell S. Fowler states that any patient, fat or thin, young or old, having mild or severe cramp in the epigastrium ordinarily looked upon as indigestion, the patient being free from tenderness over the appendix or history of tenderness over the appendix, on operation will show ninety times out of a hundred gall bladder disease and the other ten will show a surgical lesion of the appendix, stomach, liver or pancreas. If to this symptom of cramp in the epigastrium is added pain or soreness over the gall bladder or a history thereof, a diagnosis of gall bladder disease can be made with certainty.

13. Occipital Intermittent Claudication. — Tasker Howard, in presenting a case, emphasizes that the symptom known as intermittent claudication involves three factors: (1) Local arteriosclerosis with narrowing of the vessels and consequent lessening of the blood supply to the parts, (2) intermittent further narrowing of the vessels through spasm, due to a hyperirritable vasomotor system, and (3) a further relative circulatory insufficiency when the demand for blood is increased by the use of the part. In the case which he reports arteriosclerosis was obviously present, the pain was induced by physiological activity of the part or by cold, and was relieved by rest or by measures aimed at controlling arterial spasm. The vessels involved in this case are certain branches of the external carotid, particularly the occipital, with its ramifications not only up over the scalp but down to various muscles on the posterior aspect of the neck, and possibly the ascending pharyngeal.

Petty Signs of Lethargic Encephalitis.—Roger first outlines the major symptoms of this affection, including the atypical ones and then takes up the so-called

petty signs, restricting his paper to two of these, viz.: the facies of paralysis agitans, which he styles the pseudo-parkinsonian facies, and the paralysis of accommodation. These signs have sometimes enabled him to make a retrospective diagnosis. The disease usually goes through two stages, somnolent and post-somnolent or depressive, and the two signs may appear during this post-somnolent phase as well as during actual convalescence. The patient may have passed through his somnolence completely, and his ptosis disappears at the same time. It is then that we note a fixation in the lower part of the face. In repose the musculature seems atonic and the folds in the face effaced. During conversation the muscles do not show their accustomed play and mimesis is also poor. The upper face may or may not participate. The masklike effect may persist for two weeks to one month or more. The nucha at the same time is slightly rigid as indicated in part by the peculiar attitude of the head. This symptom may persist for an indefinite period and in one case one year after the disease the subject could not move his head with the normal suppleness. More rarely a parkinsonian tremor may be added. In regard to paralysis of accommodation, this has been a very uncommon symptom, the author mentioning but two cases. The subjects noted its presence after the extrinsic pareses had disappeared, when they first sought to read after the passing of the diplopia. They were obliged at this juncture to change the reading focus. A middle-aged subject had actually bought some presbyopic glasses when the disorder suddenly vanished. The light reflex was conserved. The condition persisted in full for 3 or 4 weeks and was slow in vanishing completely.

Relations Between Grippe and Epidemic Encephalitis.—Micheleau of Algiers, a forensic expert, writes exhaustively on this important subject. We have become, he says, very sceptical about the autonomy of maladies which appear to lack a causal element and definite anatomical lesions. Yet we know that diseases *sine materia* do exist. May not an unknown bacterium secrete a toxin of such peculiar tropism that it gives rise to a definite disease picture? On the other hand we have to consider the unknown *x* which is known as the *genius epidemicus*. The author seems to have been on duty in Europe with Algerian troops in the spring of 1918, at which epoch a wave of influenza appeared in Flanders. At this juncture he cared for several thousand cases of the latter malady. Among his grippe cases he saw much somnolence, a peculiar urge to sleep. The fever and other general and local symptoms seen were those of influenza. But in these cases the affection was soon over and indeed might have been termed a "three day fever" as far as the majority of them was concerned. The sleep component he thinks might have been of cosmic motivation—a reaction from the war tension which belongs under the head of the *genius epidemicus* and might conceivably be present in any malady. Under such conditions the toxins formed from any type of pathogenic bacterium might conceivably produce somnolence. The author, the better to illustrate his contention, gives two case histories which would ordinarily have passed for influenza. Later the diagnosis leaned very strongly to epidemic encephalitis. This was of the myoclonic type in one patient, while in the other case the patient first went through a grippal broncho-pneumonia, which had as a sequela a cerebral affection in which somnolence was a factor. In the absence of our present information concerning sleeping sickness, the author seems to think, both these cases would unhesitatingly have been regarded as cerebral influenza.

Hepatic Insufficiency.—Loeper discusses very thoroughly a subject that of late years seems to have shown some falling off in interest, perhaps from the demonstration that the so-called insufficiency symptoms pertain rather to the organism as a whole than to the liver alone. The liver has many functions so that insufficiently ought to manifest itself in a number of ways. The author, however, restricts the essential manifestations to three—portal hypertension, icterus and toxemia. In the first named of this triad the blood cannot traverse the liver, so that ascites and splenomegaly result from back pressure. The interference with the passage of blood increases the tension in the portal vessels before the phenomena of stasis develop. It is therefore apparent that the author uses the term hepatic insufficiency in a sense not usually accepted. We mean ordinarily a cellular insufficiency not connected with organic disease while in the author's sense is meant the secondary insufficiency of organic disease. Ascites from this angle is hepatic insufficiency. The author remarks in passing that every increase of salt in the diet means an aggravation and every reduction of salt a diminution in the ascites. The second great symptom of hepatic insufficiency is jaundice. This is not only inconstant but is not parallel with the degree of ascites; yet icterus with its secondary symptoms, like bradycardia and pruritus, does in its way indicate hepatic insufficiency. There is, however, a notable dissociation here, which shows the essential separation of the components of vascular stasis and obstruction of the gallducts, together with the phenomenon of hemolytic jaundice. In regard to hepatotoxemia this is still more complex than icterus. Passive obstruction of the portal system is a single phenomena; icterus is twofold in nature while toxemia is multifold—the author isolates three forms, viz., that due to defective neutralization of food products and the forms due respectively to absorption of bile and absorption of biliary salts. The hepatic parenchyma, however, is itself toxic, as has been repeatedly shown by animal experiment. The author, after having established a variety of hepatic toxemia which is due to absorption of bile pigment, later denies that any toxicity on the part of these has been proven.

Pathology of Edemas.—This number contains a symposium on the above subject. Achard leads off with a general paper making a distinction between the constitutional and lacunar water. The latter in edema accumulates in the great serosæ, subcutaneous tissues, etc. He then discusses the combined water-chloride retention and its control by diet. Aside from the dietetic factor the causes relate to circulatory and eliminatory insufficency. There are other less understood causes of edema seen in dyscrasias. Clinically there are sharply delimited forms, as phlegmatia dolens due to phlebitis, the cardiac form from asystole, the renal form, the so-called lipocytic or intracellular form which can be experimentally produced in animals. Therapeutically we have forms which yield to local treatment, to diet, to digitalis, to theobromine, etc. The author does not mention the recently reported successes from the use of ŏuabine in ascites. Leblanc considers the pathogeny of edema with especial reference to the lipocytic form due to increased power of imbibition of the cell. Its relationship to the other edemas is at present problematical. The property of lipoids, which are not soluble in water, to regulate the hydrophilic or hydrosyntactic power of the cell seems paradoxal. The author has sought to determine the lipemic coefficient in subjects with nephritic dropsy. Apparently there is no law of relationship between retention of water and chlorides and the lipoid content of the blood. A paper by Ameuille is devoted to the timely subject of the paradoxes of the edemas. He cites certain unusual types such as the inanition type seen in prisoners on low diet. This form is not severe, confined perhaps to swelling about the malleoli. The ordinary causal factors can be eliminated. The condition vanishes promptly when the regulation diet is resumed. It is not known that professional fasters have developed this edema. Gastinel and Boutelier discuss the semeiology of edemas of the face in very exhaustive fashion.

Thirty-second Annual Meeting, Held in Highland Falls, Ill., May 31, and June 1 and 2, 1920.

THE PRESIDENT, DR. THOMAS W. SOUTHWORTH OF NEW YORK, IN THE CHAIR.

President's Address—Segregation of Pneumonia.—Dr. THOMAS S. SOUTHWORTH delivered this address, in which he stated that more and more attention was being paid to the prevention of infectious diseases, especially such as bore particularly on the child. Here adequate separation of the sick from the well was indispensable, and the principle was capable not only of stricter enforcement, as in rural communities, but of intelligent extension everywhere into new fields. One of these was pneumonia, for which less had been accomplished in the way of limiting its ravages than for any other malady of like import except pandemic influenza. This was not due to lack of interest in the problem, but rather to its complications, since the process we called pneumonia was several pathologic entities of diverse etiology and with somewhat loosely correlated clinical manifestations. While untiring zeal had been expended to find a remedy for the pneumonias, the possibility of guarding against their inception had not been so clearly considered. One great avenue was not properly guarded and that was the exposure of susceptible individuals in dangerous propinquity to active cases of the disease. It had long been known that the pneumonias were caused by microorganisms of recognized pathogenic virulence, yet it had been their custom to treat pneumonias in the general wards of hospitals and to place about them in the home only the ordinary precautions of the sick room. Segregation of such cases might have been practiced by thoughtful individuals, but the idea had not found its way into the general medical conscience nor been advocated widely in our literature. Evidence of the infectiousness of pneumonia was not wanting. Whenever it appeared among children quarantined for measles it spread rapidly, with an appalling mortality. The writer had, therefore, for years insisted, when possible, upon the prompt isolation of the first cases of pneumonia among children having measles, with a resulting limitation of the number of cases, and had extended segregation to all the pneumonias. The question before them was whether they individually were to assume responsibility for permitting exposure of cases of pneumonia which they would not permit to much less serious types of illness, the latter having been declared quarantinable, while the pneumonias thus far had not been. The obligation was imperative to anticipate the day, not far distant, when the movement to control the scourge of pneumonia might make the retention of such cases in a general ward as repugnant to our medical sense of propriety as a case of open tuberculosis.

Studies on Blood Sugar: The Effect of Blood on Picrate Solutions; A Consideration of the Limitations of the Lewis-Benedict Method.—Drs. DAVID MURRAY COWIE and JOHN PURL PARSONS of Ann Arbor presented this paper, in which they reported a series of experiments the results of which tended to show that blood contained substances other than sugar which induced a color change in the picrate solution employed in the modified Lewis-Benedict blood-sugar method. Under normal conditions these substances did not interfere with the established normal range for this method. Under pathological conditions, however, several of these substances which showed the most marked influence were epinephrin, acetone, and diacetic acid. Creatinine might interfere but it did so in a less marked degree. As picrate solution reacted to smaller quantities of acetone than were normally found in the blood the questions might well be raised: 1. "Do not the acetone bodies of the blood contribute to the established normal blood sugar range for the Lewis-Benedict test?" 2. "As epinephrine in infinitesimally small quantities induces a color change in the picrate solution, is it not possible that this substance when thrown into the general circulation, as is supposed to happen in emotional states, may induce a so-called hyperglycemia without mobilizing the glycogen stores of the liver?"

Dr. OSCAR M. SCHLOSS of New York thought that the Lewis-Benedict method under normal conditions was probably an essentially accurate clinical method, though it might have a moderate error such as was present in any colorimetric method. He had run a series of observations, in which he had used the Lewis-Benedict method, and a control series in which the method of Bertrand was used. The Lewis-Benedict method gave results that were constantly higher, but the difference was consistent and did not influence the results of observations made in normal cases. It was quite true, however, that a marked increase in creatinine would influence the results. The relationship of acetone and adrenalin required that a careful test of the accuracy of this method be made.

Dr. COWIE said that workers on this side of the water and those on the other side had expressed very different opinions in reference to the effect of heat on picrate solutions. The experience of Addis and Benedict, as well as their own, showed that prolongation of the heat produced an increase in the intensity of the color. They had not run the acetone tests beyond ten minutes, but up to that time a color change had been produced.

Epidemic Encephalitis Lethargica.—Dr. L. E. LA FETRA of New York presented this communication, in which he reviewed the experimental work of Loewe and Strauss, and presented an analysis of 11 cases of encephalitis lethargica treated in his service at Bellevue Hospital since January 1, 1920. He said it was evident both from the difference in the lesions and also from the results of animal experimentation that poliomyelitis and epidemic encephalitis were distinct diseases. He had not found that epidemic encephalitis followed influenza with sufficient regularity to warrant one in stating that it was caused by influenza, though influenza might possibly predispose the patient to infection or increase the virulence of the prevalent virus. Of the 11 cases four died. The children ranged in age from five to twelve years. There was no relationship between any two of the patients, and they did not live in close proximity with each other. In only two cases was there any history of influenza. The symptoms were varied, but in most instances there was marked headache, accompanied occasionally by dizziness. Vomiting occurred in about one-half the cases. Two of the children were very wakeful and talkative for a day or two, and then became lethargic. The outstanding features when the disease was well under way were lethargy, general weakness, and ptosis, or paralysis of the ocular or facial muscles, with double vision in several instances. Fever was usually very slight, from 101 to 102° Fahr., and that only for a few days. Weakness of the muscles of the face gave the mask-like appearance. The muscles of the extremities had a peculiar wax-like tone, and the limbs remained in the position in which they were placed. It was noted that the fatal cases had higher white cell counts than those that recovered. The spinal fluid was under little or no increased pressure, and in some instances was perfectly normal, there being no increase in the number of cells. In most cases, however, globulin was present and there was an increase in the number of cells, the average number ranging from 50 to 100, all of which were mononuclears. In one fatal case the cell count was 275. The fluid was sterile on culture. Recovery took place gradually, there being first a return to consciousness, then a diminution of catatonia and paralysis, and last of all the asthenia and ptosis disappeared. Two patients showed seriosu sequelae, one imbecility and the other spastic paralysis and mental impairment. Undoubtedly, as with poliomyelitis, abortive, mild atypical cases of the disease occurred. Many of these probably went unrecognized. The disease was differentiated from tuberculous meningitis by the high cell count and finding the tubercle bacillus in the latter. The course in tuberculous meningitis was two or three weeks, while in encephalitis lethargica it was longer. In encephalitis ptosis and facial palsy appeared early and did not progress. In differentiating the disease from poliomyelitis, one must be guided by the epidemiology. Poliomyelitis was more apt to occur late in the summer and in the fall, and the cell counts in the spinal fluid were higher with a larger percentage

of polynuclears. In encephalitis the cells were practically all mononuclears, but that point was not absolutely diagnostic. From cerebrospinal syphilis the disease could be differentiated by the negative Wassermann and negative gold chloride tests; from brain tumor by the absence of choked disc and changes in the spinal fluid; from meningism by the absence of other diseases that would cause meningism. Meningism was likely to give an increased spinal fluid with normal findings. The mortality of the disease was about that of poliomyelitis. How great a proportion might show damage to the brain it was too soon to state. The treatment until a specific serum was produced was symptomatic.

Dr. ROWLAND G. FREEMAN of New York felt inclined to think there was some relationship between encephalitis lethargica and influenza, inasmuch as this disease was not seen until following the epidemic of influenza, when a good many cases were seen for a few weeks, and then one no longer saw them. The literature seemed to show that the disease had invariably occurred after influenza, and not after other conditions. While little was known of the ultimate results of the disease, they seemed not altogether favorable.

Dr. HENRY HEIMAN of New York thought it was sometimes impossible to differentiate between epidemic encephalitis and tuberculous meningitis if the tubercle bacillus could not be found. Loewe and Strauss had cultivated the organism of encephalitis lethargica, and had shown that the disease could be diagnosed by animal inoculation. Rigidity of the neck was not often present in encephalitis lethargica, while this symtom was usually found in tuberculous meningitis. In encephalitis lethargica the patient could be aroused while in tuberculous meningitis this was not as a rule possible. In the latter disease the cell count of the spinal fluid was high, while in encephalitis lethargica it was apt to be low, not more than 60 or 70. A cell count of 270, such as Dr. La Fetra had mentioned, was rare; their highest count in encephalitis lethargica was 87. Frequent and careful search for the tubercle bacilli should be made in every case supposed to be encephalitic lethargica, and the eyes should be examined to detect the presence of choroid tubercles.

Dr. CHARLES GILMORE KERLEY of New York said the great variability of the symptomatology was the outstanding feature of this disease. There was only one symptom that was constant, and that was the high degree of stupor resembling an opium narcosis. Dr. Kerley described three cases illustrating the difference in the symptomatology in this disease. One of these cases was of particular interest because the patient, when well on the way to recovery, had a relapse, and was now recovering from the relapse. This case he thought was very unusual.

Dr. JOHN HOWLAND of Baltimore thought the disease more common than was generally believed; in its atypical forms it was apt to pass unrecognized because of the relatively slight changes in the cerebrospinal fluid. They had had thirty or forty cases of the disease under their care, and had found the symptoms very irregular, though it was scarcely necessary to mention that point. Sequelae might persist for a long time. Four patients who had suffered from acute symptoms for periods ranging from six weeks to three months were under observation at the present time on account of abnormal symptoms, particularly at night. They were apparently normal in the day time, but were sleepless and restless at night. This sleeplessness might last for weeks. As time went on more atypical cases and more of the sequelae of this diseases would probably be seen.

Dr. ISAAC ABT of Chicago told of a child presenting the classical symptoms of encephalitis lethargica, who after a time became restless. A second lumbar puncture was made, which showed an increased number of cells and a turbid fluid. It was found that the child had a brain abscess. There seemed to be a tendency to center attention on this form of encephalitis and to forget or overlook the other forms.

Dr. DAVID MURRAY COWIE asked if any cases had been cared for in the wards of general hospitals, and, if so, whether the disease had spread.

Dr. OSCAR M. SCHLOSS of New York said that although encephalitis never occurred to the degree that it had during the recent epidemics, it occasionally occurred as a complication of measles and scarlet fever. Last winter he saw two cases following measles in which the encephalitic was typical. Sporadic case had been seen for some years, in which the symptomatology was practically that of "encephalitis lethargica."

Dr. LA FETRA, in closing the discussion, further emphasized the points brought out in reference to the differential diagnosis of encephalitis lethargica, and stated that undoubtedly the same symptoms could be produced by other germs and viruses, such as were seen in a meningitis complicating scarlet fever or the so-called X disease of Australia. As to whether the disease was contagious, they had made an effort to isolate the cases, but a few had been taken into the ward under the impression that they were tuberculous meningitis and in no instance was there a secondary case.

Acute Cerebrocerebellar Ataxia: With Reports of Cases.—Dr. J. P. CROZER GRIFFITH of Philadelphia presented a résumé of 17 cases previously reported pointing to an involvement of the cerebellum as well as to other parts of the brain and added three new cases. The first case exhibited incoordination, nystagmus, affection of speech, confusion of mind, increased knee jerks, but no paralysis. This patient made a rapid and complete recovery. The second patient had a staggering gait, dizziness, incoordination, but no nystagmus or affection of speech. This child continued to show incoordination three and three-quarter years later. The third patient exhibited a staggering gait, nystagmus, vertigo, affection of speech, and mental backwardness. The eye grounds were normal. A year later the symptoms were still present, but in a much less marked degree. A fourth patient showed symptoms suggestive of encephalitis lethargica. While convalescing, marked incoordination and affection of speech became manifest, and recovery was very slow. The affection of speech still persisted. The conclusions drawn from these cases and from those collected from the literature was that this condition in which acute hemorrhagic encephalitis involved the cerebellum, though not common, was certainly more frequent than was supposed. It might be designated "acute cerebellar encephalitis" because symptoms indicating the involvement of the large brain were always present, though the degree to which the processes involved one or another part of the brain varied with the case. The cause of cerebrocerebellar encephalitis varied decidedly. In the majority of the cases reported, however, some infectious disease preceded the attack. This was true in two of the cases reported in this paper, while in the other two no such connection could be found. The prognosis so far as life was concerned seemed good, and so far as statistics went it appeared that the disease left no traces in the majority of instances. In all the cases reported lumbar puncture was done and was always negative.

The Significance of Xanthochromia of the Cerebrospinal Fluid, with Report of a Case.—Dr. ISAAC ABT of Chicago reported this case because of the yellow coloration of the spinal and ventricular fluid. The infant was thirty-seven days old at the time of death, and was of eight months' gestation. Interest also attached to this case because of the occurrence of bronchopneumonia and pyelitis. Xanthochromia was found in the complete syndrome of Froin and in the incomplete syndrome of Nonne. Froin's syndrome included massive coagulation, while Nonne's syndrome included increased globulins, but not massive coagulation. The importance of cell increase was mentioned by some and ignored by others. Xanthochromia was most frequently found in cases of tumor, inflammation, or trauma cutting off part of the spinal canal. The cul-de-sac so formed usually contained a yellow fluid which coagulated *en masse*. The pigment came from the blood ultimately. In addition to the process of transudation which occurred in a cord compression, it was readily seen that any condition which permitted red blood cells to escape into the spinal fluid might produce a yellow color when the red cells had been dissolved and the hemoglobin freed. The globulins were always increased in a yellow fluid, whether massive coagulation occurs or not. Xanthochromia might be due to transudate in the case of a tumor pressing on the cord; exudate

in the case of meningeal inflammation, and hemorrhage in cases due to trauma, inflammations, and tumors. Increased cell count occurs in cases of meningitis, and is also found in cases of tumor and hemorrhage. In the last case the presence of red cells usually excluded other conditions, although blood might be present as a concomitant finding in tumors and meningitis. Pellicle formation was of little importance, being usually found in meningitis, though it had been reported in a case of tumor without meningitis. Where the process had been of short duration and compression had not been sufficient, massive coagulation might not occur. In fact, many writers stated that Nonne's incomplete syndrome was merely a precursor of Froin's complete syndrome. Some cases of Nonne's syndrome probably never reached Froin's stage. Similarly, conditions causing hemorrhage might never give sufficient plasma and fibrin to cause coagulation. Another class of cases causing a yellow spinal fluid was that type associated with red cells in the fluid. Many considered this a separate syndrome, and applied to it the name erythrochromia. It was shown by quotations of cases from the literature that no hard and fast line could be drawn between yellow fluids on the basis of the presence of red cells. The other differences which were stated as distinguishing erythrochromia from xanthochromia were proved to be not differences at all, because such properties as variability of a single fluid as regards color and globulin content applied just as well to one as to the other. The case reported was that of a child brought to the hospital as a feeding case. About the fourteenth day the temperature rose to 106° Fahr., and the child was seized with severe convulsions. The urine showed pyelitis, and upon examining the lungs patches of bronchopneumonia were found. The convulsions, and urinary and pulmonary findings persisted until the end. The anterior fontanelle was tense and bulging. On the thirtieth day spinal puncture yielded 4 c.c. of distinctly yellow fluid. The fluid was clear, but the first 2 c.c. yielded a filmy pellicle. The second tube, containing 2 c.c., did not change. Three days later the right ventricle was punctured and 20 c.c. of yellow fluid was removed. In both specimens of fluid there were red cells, increased globulins, and increased cell count, most of which were polymorphonuclears. The child died on the thirty-seventh day, and autopsy showed a fibrinous, hemorrhagic meningitis and encephalitis. There were numerous subpial hemorrhages, a marked internal hydrocephalus, sub-acute pyelitis, and bronchopneumonia. Two other cases were quoted from the literature, in which ventricular punctures were performed. In one of these the fluid was yellow and the condition was due to a tumor of the pineal gland. In the other the fluid was colorless and the yellow color of the spinal fluid was due to a tuberculous mass at the foramen magnum. Previous to this case the youngest case on record of xanthochromia of the cerebrospinal fluid occurred in an infant of nine months. The case reported was one illustrating the second type of xanthochromia. Both the spinal and the ventricular fluids were yellow and both contained red blood cells.

Dr. J. MILTON MILLER of Atlantic City recalled a case which he had reported before the society three years ago, a child three weeks old with meningitis. The first and second lumbar punctures were negative. Finally a ventricular puncture was made and a yellow gelatinous fluid obtained, but it did not coagulate.

Nature of the Reducing Substance in the Urine of Children Suffering from Nutritional Disorders.—Dr. OSCAR M. SCHLOSS of New York read this paper, in which he reviewed the work of Langstein and Steinits, which had led them to believe that the reducing substance in the urine of children suffering from nutritional disturbances was lactose or galactose. Experiments which he had carried out did not confirm this finding. The only reducing substance which he had found constantly present in perceptible amounts was glucose. There was usually a nonfermentable reducing substance similar to that found in normal urine. This might be lactose, but its amount was too small to identify it with certainty.

Dr. DAVID MURRAY COWIE of Ann Arbor asked whether in the cases in which he did not find a fermenting substance like glucose or lactose he had run the acetone test.

Dr. HENRY HEIMAN of New York asked whether an attempt had been made to exclude glucose and then to test for pentose and galactose.

Dr. SCHLOSS replied that the acetone and creatinine would of course be present in the nonfermentable fraction. Both substances were excluded, the acetone by boiling the urine and the creatinine by first precipitating with mercuric nitrate solution. If pentose were present it could only be in the non-fermentable fraction. The proportion was so small it was difficult to determine its presence with any degree of certainty.

Bodily Mechanics; Its Relation to Cyclic Vomiting and Other Obscure Intestinal Conditions.—Drs. FRITZ B. TALBOT and LLOYD T. BROWN of Boston presented this communication, in which they called attention to the fact that faulty bodily mechanics was responsible for a great loss of efficiency among adults during the war. Under the strain of training and of war many men broke down in France. As they could not be sent home they were given special training which restored 80 per cent. to full physical efficiency. The lack of proper training during the growing and formative period of life had cost the British government a great deal of money during the war, and also much anxiety as to how to obtain the required man power. The physical examination of 700 men entering Harvard University showed that 80 per cent. had bad bodily mechanics, and only 20 per cent. had good bodily mechanics. Time spent on training during childhood brought more far-reaching results in the correction and prevention of poor bodily mechanics than the same time spent on adults. Poor bodily mechanics was responsible for three abnormal conditions in childhood. Correcting improper posture often corrected chronic constipation, hastened the cure of recurrent vomiting, and cured certain types of attacks of acute abdominal pain in children. It therefore seemed that posture must be the principal cause or the principal contributing cause of these conditions. Illustrative cases were cited.

Dr. CHARLES GILMORE KERLEY of New York said it seemed to him that it was a faulty structural condition rather than the faulty mechanics that was the primary cause of these troubles. He asked Dr. Talbot whether he had made an *x*-ray study of the intestinal tract in these cases. He said he asked this because he had been studying along these lines and had found practically the same things true except that an *x*-ray study usually revealed a defect in the intestinal tract. In these cases one almost invariably found an elongated sigmoid, and associated with the elongated sigmoid and faulty posture one found all sorts of intestinal disturbances. An abdominal belt worked wonders.

Dr. GODFREY R. PISEK of New York expressed the hope that this paper would be brought to the attention of the general practitioner rather than to that of the pediatrist. The work of the orthopedist was important in these cases, but alone it would not be successful, because an orthopedic appliance was only for temporary use until the child's general nutrition could be improved. In attempting to correct the poor posture a lead tape showing the change in the curves of the back, chest, and abdomen when in proper and improper posture was a gerat help.

Dr. L. E. LA FETRA of New York called attention to the work of the American Posture League established by Dr. Goldthwaite of Boston. This organization had for its object the encouragement of proper posture in school children. Prizes were awarded to those who had the best posture. The results of a number of years of this propaganda would undoubtedly be excellent.

Dr. DEWITT H. SHERMAN of Buffalo suggested that in the treatment of bad posture it was advisable to go a little further than either the orthopedist or the surgeon did and to institute abdominal massage. A return to normal condition in these patients would be greatly expedited by a proper use of massage.

Dr. D. J. MILTON MILLER of Atlantic City recommended, in addition to the other methods used in the treatment of these cases, rest on the back or right side for an hour to an hour and half during the day, preferably after meals.

Dr. HENRY HEIMAN of New York spoke of the part played by bodily mechanics in the production of orthostatic albuminuria. The correction of faulty posture was most important in overcoming this condition.

Dr. RICHARD M. SMITH of Boston emphasized the necessity of following up these children after they had been taught correct posture, owing to the fact that there was a constant tendency to relapse into their faulty habit. Belts and exercises were important as reminders of the necessity of maintaining a correct posture.

Dr. TALBOT, in closing the discussion, stated that *x*-rays of the intestinal tract were taken in most of the cases, and in a number elongated colon was demonstrated. In some instances, if the child was lying down the *x*-ray would show almost nothing, but if the child stood up there would be a great deal of ptosis. The same individual might assume both a good posture and a poor one, and it had been shown that the colon might be 5 inches higher when the individual was in the good posture than when in the poor one. The most important thing in these cases was to keep the patient in your own hands and to guide the treatment. The next most important thing was to prevent fatigue, since fatigue caused poor posture and poor posture caused fatigue, thus establishing a vicious circle. The belt alone would not do everything; with it there must be proper curative exercises, and these latter formed a very important part of the treatment. He was glad Dr. LaFetra had brought out the possibility of preventive work in the schools. Personally he felt that this was one of the most important things that should be undertaken in connection with school hygiene. The rest treatment to which Dr. Miller referred was most essential, and should be taken on the back with the hips raised so that the abdominal organs would fall within the abdomen. The question had been brought up whether these children would not get well without treatment. If one weighed all the factors it seemed to him that they recovered sooner if properly treated than they would have done if untreated.

A Brief Case Report of an Epidemic of Hemorrhagic Diarrhea Due to the Streptococcus Mucosus.—Dr. A. D. BLACKADER of Montreal read this paper. He stated that he was called to Waterloo, a town sixty miles southeast of Montreal, because of an epidemic of diarrhea. On March 22 the first case was reported; on the following day five additional cases were reported, and reports continued to come in until 65 cases were recorded in the town itself and a number within a short radius. About one-fourth the entire number of cases occurred in adults, though the larger proportion were in children under six years of age. High fever, nervous symptoms, and vomiting ushered in the attack and diarrhea set in early. Mucus and blood appeared in the stools and increased rapidly in amount until they composed almost the entire stool. The attack lasted from a few days to fourteen to twenty-one days in some cases. The temperature in the severe cases went as high as 106° Fahr., while in the milder cases it was comparatively low. Notwithstanding the severity of the attacks no deaths occurred. Careful examination of the stools in two cases showed *Streptococcus encapaulatus* and colon bacilli in one, and in the other large numbers of *Streptococcus mucosus*. Few other bacteria were found and no organisms of any of the types of *Bacillus dysenteriæ*. An inspection of the milk supply and a study of the situation seemed to eliminate this as the source of the epidemic. The water supply of the town came from springs, and inspection indicated that several of these were insufficiently protected against contamination. The epidemic occurred after a few days of pronounced warm weather when the snow melted rapidly on a still frozen soil. The absence of any of the *Bacillus dysenteriæ* indicated that the streptococcus must be the chief organism concerned in the production of the epidemic.

Phlyctenular Ophthalmia and Its Relation to Tuberculosis.—Drs. BORDEN S. VEEDER and T. C. HEMPELMANN of St. Louis presented this paper which was read by Dr. Hempelmann. He stated that among pediatricians the impression was widespread that phlyctenular ophthalmia was closely associated in some way with tuberculosis, but as yet many ophthalmologists were unwilling to concede this relationship. In order to throw additional light on this question, 196 children with phlyctenular diseases were subjected to a careful study to determine the possible presence or absence of tuberculous infection. Skin tuberculin tests were positive in over 92 per cent. of the 196 children. The results of the complement fixation test for tuberculosis were strikingly similar to those obtained in cases of proved tuberculosis. In over one-half the cases tuberculous lesions involving other organs than the eye were definitely demonstrable. Children observed for periods of one year or more showed an even greater proportion of tuberculosis lesions, more than four-fifths giving evidence of tuberculosis. The study revealed an intimate relationship between these two diseases, but brought out no other points bearing on the etiology of phlyctenular ophthalmia.

Dr. JOSEPH BRENNEMANN of Chicago stated that Dr. Gibson and he had done a piece of work similar to that just reported and found a positive tuberculin test in something like 98 per cent. of the cases of phlyctenular disease. He had seen a great many of these cases in dispensary but not in private practice. Before making this investigation he had thought phlyctenular ophthalmia was not a tuberculous disease, but he now felt that it was either a manifestation or an accompaniment of tuberculosis. Finding phlyctenular ophthalmia was not, however, sufficient ground for stating that the child had tuberculosis.

Dr. HENRY J. GERSTENBERGER of Cleveland suggested suggested that the exudative diathesis might have something to do with phlyctenular ophthalmia. Many tuberculous children, if one took a careful history, would be found to have had eczema or intertrigo. These two factors might also play a part in the etiology of the conditions near discussion.

Dr. FRITZ B. TALBOT of Boston stated that in a series of 100 cases of phlyctenular ophthalmia at the Massachusetts General Hospital, 21 per cent. showed other signs of tuberculosis, such as adenitis, bone tuberculosis, or pulmonary tuberculosis. The von-Pirquet reaction was positive in all the chronic cases of phlyctenular ophthalmia, though many of them showed no other signs of tuberculosis.

Dr. B. RAYMOND HOOBLER of Detroit described work that he had done on this subject in association with an ophthalmologist in a large clinic. They had found injections of old tuberculin in small but increasing doses one of the most satisfactory methods of treating this condition.

Dr. HEMPELMANN said he had been very much interested in the work Dr. Gibson and Dr. Brennemann had done, and he had merely wished to carry the clinical investigation a little further. The object of this paper was to get the ophthalmologists to recognize the relation between phlyctenular disease and tuberculosis, so that they would recognize the need of general care for these children. As to the exudative diathesis, they had obtained very slight history of lesions attributable to that condition in this series of cases. Such statistics as they had obtained showed that phlyctenular ophthalmia was no more frequent in children having exudative diathesis than in others. They had studied the effects of tuberculin in the treatment of phlyctenular ophthalmia, starting with doses of one-millionth of a mg. of old tuberculin. The ophthalmologists were not convinced that either local recovery or general improvement resulted. In this series of cases the ones giving negative reactions were mostly those in whom the test was not repeated and in which no intracutaneous test was made.

A Study of Pneumonia During the Recent Epidemics.—Dr. HENRY HEIMAN of New York presented this communication, which consisted of an analysis of a series of 336 cases of pneumonia admitted to the Pediatric Service of Mt. Sinai Hospital during the pandemic of influenza. Of these cases 48 were lobar and 288 bronchial pneumonias. Not all were influenzal pneumonias. The mortality for the entire series was 16.6 per cent. Though a variety of organisms were found in the sputum, including the influenza bacillus, pneumococcus, streptococcus and staphylococcus, none was sufficiently prominent to justify conclusions. The most frequent complication was otitis media which occurred in 75 of the 336 cases. Empyema developed in 17 cases. In the presence of this complication, he advised against early operation before the acute stage of the pneumonic process has subsided. Hygienic care, efficient nursing, plenty of fresh air, a bright sunny

room, quiet surroundings and close supervision were of prime importance in the treatment of pneumonia in children. A cleansing bath should be given each morning as a protective measure, and vigilance should be exercised to guard against infection of the eyes, skin and mouth. While fresh air was very necessary, he did not favor the cold air treatment. The digestive tract should receive the closest attention. For the moderately severe cases with high temperature, hydrotherapy might be employed in the form of warm packs. Atropine and adrenalin might be indicated in the toxic cases. The promiscuous use of dry cupping might be regarded as a demonstration of spectacular therapeutics of no real value. The general use of digitalis he could not recommend in children; as a rule the pulse was not lowered or the blood pressure raised by this drug. It was to be hoped that there would be a further differentiation of types of pneumonia in infants and children with the hope of securing specific therapy.

Dr. GODFREY R. PISEK of New York stressed what Dr. Heiman had said with reference to allowing an empyema to develop fully before subjecting the child to operation. He thought the pediatrist was the one to decide as to the proper time to operate.

Dr. J. P. CROZER GRIFFITHS of Philadelphia said they had seen a great deal of pneumonia in 1918 and 1919, in the influenza epidemic which struck them with unusual severity. Everyone, however, was struck by the fact that the number of children suffering from it was small as compared with the number of adults, and that the disease in them was not nearly so severe. In the epidemic of influenza in 1919 and 1920, which was much less severe than the former one, there were a large number of cases of pneumonia occurring in children and a high mortality rate. This was true both in the wards of the Children's Hospital and in the cases seen in consultation in private practice. There was a marked absence of leucocytosis. The organism most often found was the hemolytic streptococcus. They had noted, too, that it was extremely common to have empyema develop, and that it came on very insidiously. It was present so often in cases that ordinarily would have been diagnosed as free from this complication that puncture was done as a precautionary measure, and repeatedly such cases would show fluid. Perhaps the question when to operate was a surgical matter, yet it was a question which had been put to them and one which they had been unable to answer. Many cases during the past winter had not shown the usual drop of temperature with the sudden rise, but had developed empyema while the pneumonia was still present.

Dr. ROWLAND G. FREEMAN of New York claimed that there was no method of treating pneumonia as valuable as fresh air, and the colder the air the better. In cold fresh air the patient took his food better and ran a lower temperature. He had never seen a patient harmed by cold air, and he had seen a great many helped. He did not think whiskey was indicated in younger children, though it might sometimes do good in older children. In one children's institute in New York they used whiskey whether the physician ordered it or not, and the results were not good. Dr. Freeman said that for many years he had not used digitalis in children, but was now using it in large doses and found it very valuable, especially in older children when given early.

Dr. JOSEPH BRENNEMANN of Chicago brought out the point that statistics based on hospital experience were very different from those in private practice; there was no such high mortality in private practice. A hospital ward was not a good place for children suffering with pneumonia. Another factor that vitiated hospital statistics on pneumonia was the fact that nearly every baby suffering from severe malnutrition had a pneumonia as a terminal condition.

Dr. A. D. BLACKADER of Montreal said that in Montreal they had found that hospital statistics concerning pneumonia and those from private practice represented two entirely different phases of the disease. In Montreal the mothers would not have their children in a hospital if they could keep them at home. Alcohol should not be used in every case of pneumonia in infancy and childhood, but there were cases in which it might be used. If given it should be prescribed in carefully regulated dosage as a drug. Digitalis upset the stomach, and any drug that had this effect should be used cautionsly. In children the cardiac muscle was fairly strong, so that digitalis was not needed. While fresh air was desirable, the line should be drawn at flowing air and drafts. Rest was most important, and for this reason hydrotherapy should be used with moderation.

Dr. RICHARD M. SMITH of Boston emphasized the importance of conserving the out-go of energy in the treatment of pneumonia, and for this reason he thought it a good plan to give codeine in some form.

Dr. E. W. SAUNDERS of St. Louis recommended iodide of potassium as a means of liquefying a tenacious sputum that blocked the bronchial tubes and was instrument in keeping the temperature high.

Dr. HEIMAN, in closing the discussion, said he had not attempted to give a formula for the treatment of pneumonia. He had simply attempted to generalize and suggest remedies that, while they might do no good, would certainly do no harm.

Further Progress in the Study of the Relative Efficiency of the Different Mercurial Preparations in the Treatment of Congenital Syphilis in Infants and Children as Determined by a Quantitative Analysis of the Mercury Elimination in the Urine.—Dr. WALTER R. RAMSEY and O. A. GROEBNER of St. Paul presented this paper which was read by Dr. Ramsey, who stated that the treatment of syphilis with the different mercurial preparations was still a haphazard affair, the rule being to give as much mercury as the patient would tolerate without salivation or diarrhea. Assuming that the amount of mercury eliminated in the urine during a given time would give a fair index of the amount in the circulation, Ramsey and Ziegler made some experiments, the report of which was read before the society in 1918 and printed in the *American Journal of the Diseases of Children* in the November number of the same year. In these experiments it was demonstrated that mercury, whether given by inunction, by mouth or by hypodermic injection, was eliminated in the urine in appreciable amounts. Where only one dose was given by any of these methods mercury continued to be eliminated in the urine for a variable time, and in one case as long as ten days. In this new series of experiments, they had sought to determine with some degree of accuracy the amount and rapidity of absorption and elimination of the mercurial preparations in common use, as determined by quantitative estimate of the amounts eliminated in the urine. The method was the same as employed in the previous experiments. It would be observed that where 50 per cent. mercurial ointment was used the elimination began soon after administration, the maximum elimination occuring during the following three days, the elimination being fairly complete within five days. With the 33⅓ per cent. mercurial ointment, even when double the quantity was used, the elimination did not begin in appreciable amounts until the second day after inunction and then in much less quantities than when the 50 per cent. ointment was given. When the mercurial ointment was simply used by smearing on the skin, without rubbing, the amount eliminated was much less than when used as an inunction. In the case of calomel ointment it would be seen that the elimination was delayed and the total quantity eliminated was much less than with the mercurial ointment, although two grams was used for each inunction. With mercurial salicylate in oil, used hypodermatically, it would be seen that the maximum elimination was in the first twenty-four hours, smaller quantities continuing to be eliminated for six or seven days. The mercuric chloride solutions used hypodermatically continued to be eliminated in amounts not sufficient to be measured for six or seven days. In one case there was an appreciable amount of protein in the urine following its use, a point which was mentioned in our last publication. Calomel and gray powder by mouth were apparently not absorbed to any great extent, the calomel being absorbed, however, to a much greater degree than the gray powder. It did not seem to make any difference whether the calomel was given in one or divided doses, the elimination was the same. The practical deductions which might be drawn from this series of experiments were therefore as follows: (1) Mercurial ointment, 50 per cent., was to be preferred to the less concentrated and should be repeated

not more often than twice weekly instead of daily. (2) Calomel ointment was absorbed, but less rapidly, and to a less extent than the mercurial ointment, and should therefore be given in greater concentration twice weekly. (3) The salicylate of mercury in oil should be given hypodermatically twice weekly instead of once. (4) The mercuric chloride by hypodermic injection, although the dose was very small, continued to be eliminated for several days, but owing to the fact that its use was frequently followed by the appearance of protein in the urine it should be excluded in the treatment of syphilis. (5) Calomel by the mouth was absorbed in small amounts and continued to be eliminated for a considerable time so that it was probable that it would be sufficient to give it at intervals of several days without producing diarrhea. (6) Gray powder was absorbed to a small degree and eliminated rapidly, so that fairly large doses, repeated daily, would probably be necessary to maintain mercury in the circulation. In one case of congenital syphilis treated by inunctions, not repeated oftener than once weekly, the clinical progress was apparently not less satisfactory than in cases where daily inunctions were given.

A Study of the Incidence of Hereditary Syphilis.—Dr. P. G. JEANS and Dr. J. V. COOKE, St. Louis, made this study aided by a grant from the U. S. Interdepartmental Social Hygiene Board. The method used was the histological examination of a series of placentas, together with a Wassermann reaction on the fetal blood collected from the umbilical cord at birth. In order to determine the reliability of such a method it was necessary to secure additional Wassermann reactions on the mother, and on the infant after two months in as many cases as possible. It had been shown that there was a high percentage of agreement between the results of the Wassermann reaction on the maternal blood and histological evidence of syphilis in the placenta. The necropsy findings in still born infants likewise corresponded closely with the placental histology in so far as syphilis was concerned. The writers had hoped therefore that a similar close agreement could be demonstrated between the placental histology and fetal blood Wassermann on the one hand, and the living infant on the other, in which case the incidence of hereditary syphilis in the middle and upper classes could be estimated by examination of the placenta and cord blood. Their material collected from several sources included about one-fifth the children born in St. Louis over a period of months, almost equally divided between charity and private patients. The results presented were based on data thus far collected from the first thousand cases. Up to the present time they had examined 129 infants at two or more months of age. Of these 10 per cent. presented undoubted evidence of syphilis, and the remainder were just as evidently non-syphilitic. Classification of this group according to race showed an incidence of 15.8 per cent. among negroes and 5.5 among whites. The histological examination of the placenta as to the presence or absence of syphilitic changes corresponded to the established diagnosis in 95.5 per cent. of the cases. The lack of correspondence consisted entirely in finding no syphilitic changes in the placenta in cases in which the infant had syphilis. In every instance in which the placenta was noted as showing syphilitic changes the infant was found later to have syphilis. In this group of cases in which the diagnosis was established, the Wassermann reaction on the placental cord blood corresponded to the diagnosis in the infant in 96.5 per cent. Here also the discrepancies were entirely due to finding of a negative Wassermann reaction in the fetal blood in instances in which the infant was syphilitic. In every instance in which the fetal blood gave a positive Wassermann reaction the infant was later found to have syphilis. Of the 1,000 cases, 574 were of the dispensary or poorer class, and in this group there was an estimated incidence of syphilis in 9.6 per cent. Classified according to race, the incidence among negroes was 14.4 per cent. and among the whites 5.8 per cent. The observations tend to confirm the reliability of the method of estimation and establish the justification of applying either or both methods of estimation. Among private patients able to pay a physician's fee and private room rates in a hospital, the estimated incidence based on examination of placentas was 1.4 per cent. Including the doubtful cases the incidence was 1.9 per cent. Estimating the incidence from the Wassermann reaction on the cord blood the incidence was found to be 1.6 per cent., again showing the close agreement between the two methods. In some instances in which the infant had syphilis the maternal Wassermann reaction alone was positive, in others the placenta alone. Therefore, in order to give a clean bill of health to an infant at birth it was necessary to have all three examinations negative, that was, maternal Wassermann reaction, placenta, and cord blood, and even then there might be some uncertainty. The fact that the treatment of the mother during pregnancy will result in a non-syphilitic child had been proved by other observations. In this series this observation had been confirmed. It was their feeling that the whole group fairly represented a cross section of the population of St. Louis and if such was the case the incidence of hereditary syphilis at the time of birth was 6 per cent. When syphilitic changes were present in the placenta the infant was syphilitic even though the Wassermann reaction was negative on the fetal blood, and vice versa; the infant had syphilis if the cord blood showed a positive Wassermann even though the placenta appeared normal. The infant might be syphilitic if both placenta and cord blood were negative. A syphilitic child might be born to a woman with a negaitve Wassermann, and a mother with untreated syphilis and a strongly positive Wassermann reaction might have a healthy child.

Dr. H. J. GERSTENBERGER of Cleveland stated that in going over their records of 20,000 patients treated since 1906, they had found an incidence of syphilis of 14 per cent. They had found the highest percentage among poor whites of American ancestry, the next highest among negroes, then Italians, and the fewest number among Jews. During the last six years they had been checking up their clinical diagnosis by the Wassermann test, and had found very little difference in the incidence as determined clinically alone and since the Wassermann test was being employed; what little difference there was being in favor of the Wassermann test. Dr. Gerstenberger cited an instance of twins, eight weeks old, one of which showed the skin manifestations of syphilis while the other was perfectly normal. The Wassermanns corresponded with the clinical findings. Both children were still alive and the Wassermann reactions still remained the same.

Dr. HENRY HEIMAN of New York asked Dr. Jeans what his experience was with cases of congenital lues subjected to treatment and then a second Wassermann test made. Some thought that in these cases of congenital lues "once a positve Wassermann always a positive Wassermann."

Dr. L. R. DEBUYS of New Orleans pointed out the necessity of making a Wassermann test on each individual infant no matter what the mother's reaction might be.

Dr. LANGLEY PORTER of San Francisco referred to a small series of cases tested at the Sloane Maternity in which they had had some difficulty with the anticomplementary properties of the cord blood. They had found an incidence of syphilis of 6½ per cent. With one exception in the luetic cases the placenta showed changes both grossly and microscopically.

Dr. JEANS stated that statistics based on clinical examination always gave a lower incidence of lues than those based on the Wassermann reaction. With reference to the serological cure of congenital lues, they had been getting a negative serological result in every instance in which the child came for treatment for the required length of time, so that he could say that it was not only possible to get a negative serological result in congenital lues, but that it was the rule under proper treatment. They had found the placental blood becoming anticomplementary in so few instances that they had not thought it worth while to report that finding.

Preliminary Observations on the Pathogenicity for Monkeys of the Bacillus Abortus Bovinus.—Drs. E. C. FLEISCHNER and K. F. MEYERS of San Francisco presented this communication in which it was stated that the intravenous injection of known strains of *Bacillus*

abortus bovinus produced in monkeys a definite symptom complex characterized by irregular temperature, loss of weight and positive agglutination reactions. At post mortem it was possible to recover the organisms from the spleen, lymph nodes and kidney of the infected animals. While this type of infection was interesting from the sicentific standpoint, deductions as to the possible danger incurred when large numbers of the bacteria entered into the intestinal tract could only be drawn by feeding the organisms. Macacus monkeys were fed daily over varying periods of time with cultures of known virulent strains. Using the *B. abortus* as an antigen agglutination reactions became positive, and on sacrificing the animals the infecting bacilli were found in the spleen, lymph nodes, and kidneys. A goat was infected by injecting into the udder a very virulent strain of *B. abortus* recovered from a hog suffering from abortion disease. The muscles of this goat were fed to a Macacus monkey for fifty-two days. A positive agglutination reaction developed and at post mortem the spleen and lymph nodes were enlarged, and enormous numbers of *B. abortus* were recovered from the viscera. It seemed reasonable to assume that the *B. abortus bovinus* was pathogenic for monkeys that had been fed virulent strains of the organism in large numbers. It was known that abortion disease was much more prevalent among cattle than bovine tuberculosis. For many years there had been a tremendous economic loss because we thought we must eradicate bovine tuberculosis. *B. abortus bovinus* did not seem to be pathogenic for human beings, and he did not wish to leave the impression that we must eradicate abortion disease from cattle at the present time.

Lesions in the Mid-Brain; Report of a Case.—Dr. J. H. MASON KNOX, Jr., read this paper in which he stated that because of the compactness of the structures in the mid-brain and because of its many complicated connections the study of disturbances in this region was often puzzling. The case reported was therefore interesting because the symptoms were comparatively definite and the pathological findings fairly circumscribed. The patient was a colored boy of three years, brought to the Harriet Lane Home of Johns Hopkins Hospital, February 3, 1915, because of general weakness, trembling, and drooping of the eye-lids. The family and personal history of the patient were negative, the boy having appeared perfectly normal until six months before admission, when he stopped crying almost completely. Physical examination showed enlargement of the epitrochlear glands and the eye symptoms. The pupils reacted to light, the left better than the right; there was occasional lateral nystagmus of the right eye; marked bilateral ptosis of the eyelids, apparently equal on both sides, and a definite deviation of the eyeball to the right. Two weeks later the patient returned with the history of having had two attacks of paraplegia, and of having become very weak after the second one. The symptoms referred to persisted until his death forty-two days after coming under observation. The acquired ptosis and the curious tremor of long standing noted in the extremities, together with the gradually developing paralysis of the movements of the eye-balls, except those produced by the external recti, with resulting external strabismus, in a child previously well, led one to venture the diagnosis of a tumor of the mid-brain, interfering with the nuclei of the third and fourth cranial nerves. The ataxia might also be accounted for by lesions in this region, involving the red nucleus or cerebellar tracts. Toward the end there was meningitis, probably of tuberculous origin, associated with hydrocephalus, although the tubercle bacilli was not demonstrated. A positive von Pirquet reaction and the subsequent devolpment of meningitis suggested that the tumor was probably tuberculous in origin. The post mortem findings confirmed in the main the clinical symptoms described, there being a tuberculoma the size of a hickory nut in the midbrain, involving the corpora quadrigemina and occluding the aqueduct of Sylvius. The order in which symptoms developed was of the utmost importance in reaching an accurate diagnosis. When the early symptoms were general and attributable to increased cerebral pressure, such as headache, vomiting, optic atrophy, hydrocephalus, etc., followed it might be with ptosis and oculomotor palsies, one would be inclined to place the lesion outside the midbrain, since such symptoms might result from meningitis or tumor elsewhere, possibly in the pineal gland. Whereas, as in the boy here reported, the limitation of the symptoms for months to ptosis and paralysis of the oculomotor nerves and tremor without evidence of intracranial pressure supported the diagnosis of an injury beginning in the midbrain, and, as far as it went in this case, the absence if an increase of growth or of sexual development suggested that neither the pineal nor the pituitary glands were involved.

The Ulcerated Meatus in the Circumcised Child.—Dr. JOSEPH BRENNEMANN of Chicago presented this paper, in which he stated that following circumcision there was often ulceration, scab formation, narrowing of the meatus, painful urination, and occasionally hemorrhage at the end of urination. The condition seemed always associated with the "ammoniacal diaper." The lesion was treated by the application of vaseline or wet boric acid dressings to the meatus if inflamed and prophylaxis of the ammoniacal diaper. The cause of the latter was probably a metabolic disturbance not yet fully understood but probably due to overfeeding with cows' milk fat as a result of which there was an excessive excretion of ammonium salts in the urine. In order to liberate ammonia, ammonium salts must be broken down, and as this was commonly effected by an alkali it was well to rinse the diapers well to remove all excess of soap and also to boil them for a long time to eliminate the possible influence of bacterial action.

Dr. CHARLES GILMORE KERLEY of New York stated that he had found the condition Dr. Brennemann described quite frequent in office practice. Cases of this kind he had classified as eczema of the meatus or orifice of the urethra. The treatment consisted in giving citrate of potash, applying an ointment of 5 per cent. boric acid and putting the diaper on like a T-shaped bandage. If the condition occurred in children with hyperacidity of the urine, the fats and sugars in the diet were cut down. All the cases that he had seen had occurred in children who had been circumcised. The condition was not infrequently seen in from three to six week following the operation. The cases he had seen recovered promptly under proper treatment.

Dr. HENRY HEIMAN of New York regarded the condition as purely traumatic and treated it by applying pure nitrate of silver, and avoiding irritation by the diaper.

Dr. MCKIM MARRIOTT of St. Louis expressed the opinion that the ammonia was not present in the urine when it was passed, as the kidney did not secrete a urine containing any appreciable amount of free ammonia. It was the result of the breaking down of either ammonium salts or urea. Ammonium salts were increased in certain types of feeding and these might be broken up by the action of an alkali, either as the result of soap left in the diaper or as the result of standing with alkaline soapy stools. A more important factor in the production of ammonia in the diaper was bacterial decomposition of the urine, either of the urea or of the ammonium salts. Quite a number of bacteria were capable of doing this. It could be prevented if the attempt was made to keep the child's buttocks and perineal region perfectly clean and if the diapers were thoroughly boiled.

Dr. J. P. CROZER GRIFFITH of Philadelphia advised, in order to avoid irritation of the genitals, a diaper used by a considerable number of the foreign population—one which was square, and in which the two lower corners, one on each inner side of the right and left thigh respectively, were brought up and pinned to the diaper above the hips.

Dr. JOSEPH BRENNEMAN, in closing the discussion, emphasized the fact that the ammoniacal diaper was very frequent and common with them and that he felt it was largely responsible for the condition under discussion. They had not found, as Dr. Kerley said, that the cases got well quickly; in some instances it took a long time to heal the lesion. He had passed through the stage when he believed the condition was due to eczema, to trauma or to narrowing of the meatus, and had been forced to the conclusion that the ammoniacal

diaper was the main factor in producing the lesion. He felt that the stool and bacteria, if they were involved in the production of this lesion, played a minor part.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 16, 1920.

SECTION IN MEDICINE.

DR. CARY EGGLESTON IN THE CHAIR.

THE program of the evening was furnished by the staff of the hospital of the Rockefeller Institute.

The Excretion of Urea.—Dr. DONALD VAN SLYKE made this presentation, in which he stated that in measuring the rate of urea excretion as an estimate of kidney function there were two major factors, aside from the excretory ability of the kidney, which influenced that rate, and which must be recognized and allowed for before the third factor, namely, the state of the kidney function, could be estimated. These two factors were the concentration of urea in the blood, and the rate of volume output of urine. The blood urea concentration was recognized by Ambard as a factor, and he found that other factors being equal, excretion increased as the square of the blood urea concentration, that was, doubling the blood urea would quadruple the rate of excretion. In work done by Dr. Austin, Dr. Stillman, and Dr. Van Slyke at the Rockefeller Hospital, however, it had been found that the rate of urea excretion in both man and dog was in simple proportion to the blood urea concentration, that was, doubling the blood urea doubled the output. Ambard's more complex assumption might have been due to errors in the experimental data on which his calculations were based, as the present accurate methods for blood urea determined were not then available. The second factor assumed by Ambard was the concentration of urea in the urine. He found that excretion varied inversely as the square root of this concentration. They had not been able to find any regular relationship whatever between urine concentration and rate of urea output, but had found a close relationship between *volume* rate of urine excretion and urea output. With a constant blood urea concentration, increase in the urine volume increased the rate of urea output. A larger volume, so to speak, washed out more urea. The increase in urea excretion was not entirely proportional to the increase in volume output. It was proportional to the square root of the volume, that was, in order to double the rate of urea excretion solely by increasing urine volume, the latter must be increased not twice, but four times. These relationships were expressed by the equation: $D = K\ B\ \sqrt{V}$, when D was the rate of urea excretion, K a constant characteristic within certain limits for normal individuals, B the blood urea concentration, and V the volume output of urine. When D and V were put on a per kilo basis by dividing by the body weight, W, the equation became $\frac{D}{W} = K\ B \sqrt{\frac{V}{W}}$, or $D = K\ B\ \sqrt{V\,W}$. The constant K was proportional to the rate at which the kidney excreted urea. Transposing the equation gave $K = \frac{D}{B\sqrt{V\,W}} = 7.5 \pm 3$, when D was expressed as grams of urea excreted per 24 hours, B as grams urea per liter of blood, V as liters of urine per 24 hours, and W as body weight in kilos, the value of K is 7.5 ± 3.0 for normal individuals. Normal values usually fell between six and eight; values below 4.5 were distinctly abnormal, and indicated diminished kidney function. This formula held for limits of volume output below about four liters per day. Increases beyond this point, even up to the rate of 20 liters per day, did not increase any further the rate of urea output. The rate of volume output at which further increase ceased to cause further acceleration of urea output they had called the "augmentation limit." It was characteristic for different individuals, and might vary between three and six liters. In practical application of the formula, when values of V above four liters were observed, four was used in the formula instead of the observed volume. The formula here developed had arisen from work inspired by Ambard's conceptions, and was similar in purpose to Ambard's. It had, however, he believed, been freed from quantitative errors which were involved in Ambard's equation at the beginning and had until now been left there.

Dr. HERMAN O. MOSENTHAL said this subject had been admirably handled by Dr. Van Slyke. His presentation had cleared up many of the points in Ambard's original formula which were unnecessarily complex. It was especially important to note that Drs. Van Slyke and Austin had demonstrated that the excretion of urea was not absolutely dependent upon the concentration of urea in the blood, but that the volume of urine excreted had a definite influence. The power of the kidney to eliminate any solid substance was dependent upon two factors, first, the ability of the kidney to concentrate the solid material, and, second, the amount of water that was put out in the urine. The paper, to-night, furnished very definite data as to how the normal kidney behaved in this regard; it might be a very much more difficult matter to determine the applicability of these laws in kidney disease, especially because, as had been mentioned, the ability on the part of the kidney to eliminate was really composed of two elements, the excretion of urea, and the excretion of water. An impairment of function that limited the output of either substance would entail a diminished urea output. The subject, therefore, was rather complex and did not admit of absolutely clearcut interpretation as to how the kidney was affected by the disease. In hospital work, with unlimited opportunities, the old Ambard's constant yielded results that accorded very well with the clinical picture. In private practice, as the test was formulated at present, it required too much time to be of practical value.

On Certain Differences in the Action of Strophanthin and Digitalis in Patients.—Dr. ROBERT L. LEVY read this paper, in which he said it was highly desirable to have for use in clinical medicine a safe effective preparation of the digitalis series for intravenous use. The employment of a member of the digitalis group proper had not proved feasible because of the impracticability of obtaining a preparation uniform in potency. Crystalline strophanthin, sometimes called "ouabain," obtained from the seeds of *Strophanthus gratus*, had been employed for intravenous therapy, but because of its reputed great toxicity had not been widely used in the clinic. Variations in the potency of the solutions of this drug had been observed. Such studies of its action in patients as were available were fragmentary, and the results to be drawn from them therefore inconclusive. The observations were carried out in collaboration with Dr. Alfred E. Cohn. The drug chosen was crystalline strophanthin inasmuch as it was a pure substance having definite chemical and physical properties. The crystalline substance employed was isolated from seeds of *Strophanthus gratus*, chemically identified and biologically standardized by the cat method of Hatcher. The average cat unit was found to be 0.014 mgm. per kilogram. For use in the clinic the crystals were dissolved in M/50 phosphate solution with pH 7.0, and autoclaved in hard glass ampules. In this manner alterations in reaction of the solution were prevented, and biological potency was preserved. Equivalent amounts of strophanthin by vein and of digipuratum by mouth in terms of cat units were administered to patients. In this way a series of comparable observations both in the same and different individuals was obtained. The strophanthin effects could in this way be viewed with reference to known and fairly constant digitalis standards. While the treatments were being given electrodes leading to the string galvanometer were kept constantly in place, and curves were made at intervals of fifteen minutes during the first three hours and then at one-half hour intervals for the second three hours. Another electrocardiogram was usually made the same evening and once daily thereafter until the curve had resumed the form seen in the control. Strophanthin was given usually in two doses at an interval of one hour—the first 0.4 to 0.5 of a milligram, the second 0.3 to 0.5 of a milligram. Digitalis was

administered in comparable doses and at the same intervals in the same patient on different occasions. The giving of relatively large doses, as recommended by Eggleston, had been found feasible. Rarely, however, had it been necessary in cases of auricular fibrillation to give more than one gram to produce the desired effects. Clinical observations were made on 29 cases to whom 66 courses of treatment were given. Of these 35 were strophanthin and 31 digitalis. Of these 29 cases 14 were auricular fibrillation, 12 occurring in heart disease and two pneumonia. In 15 cases the mechanism was normal. Four of these cases had heart disease, six pneumonia and five cardiorenal disease. For purposes of discussion the cases might be divided into patients suffering from auricular fibrillation and those exhibiting normal cardiac mechanism. In auricular fibrillation an effect on rate was usually obtained with strophanthin within one-half hour. Such an effect was of relatively short duration (three to seven days). The T wave of the electrocardiogram was altered less frequently than with comparable doses of digitalis, namely, in only 26 per cent. of the cases observed; and the action on the heart muscle, of which the T wave might be regarded as an expression, occurred later and disappeared earlier than the effect on conduction. With digitalis the initial effect on the rate was observed in about three hours after beginning its administration, the maximal effect being reached in about ten to eighteen hours. This effect persisted for a considerably longer time than was noted with comparable doses of strophanthin (thirteen to sixteen days). The T wave of the electrocardiogram showed the characteristic change in 90 per cent. of the cases. In patients with normal mechanism the rate was affected by strophanthin in four of sixteen observations. T wave changes occurred about as infrequently (30 per cent.) as in the cases of auricular fibrillation, and the effect on conduction occurred in a like percentage of cases and usually outlasted the effect on rate. No serious untoward effects were observed after strophanthin. The onset of abnormal rhythms, namely, ventricular premature beats and ventricular ectopic tachycardia, occurred in 52 per cent. of fibrillators and in 12.5 per cent. of cases with normal rhythm. Such toxic effects occurred always within twenty minutes of the injection of the dose causing them, and disappeared within eight hours. Nausea and vomiting were noted in 10 per cent. of cases. Comparable doses of digitalis by mouth caused undesirable effects in a much smaller percentage of observations.

Dr. HAROLD E. B. PARDEE stated that he considered this an extremely valuable study on the action of digitalis, and that it must have involved a great deal of work. The first part of the work must have taken a number of months. It was extremely interesting to see that strophanthin was different from digitalis in its effect on the T wave. There must, however, be further investigations before they could understand exactly what was meant by this effect on the heart muscle. Considering his own observations on the T wave following the administration of digitalis, Dr. Pardee said he was interested to hear that Dr. Levy noticed the effect on the T wave only after twenty-four-hour intervals. The reason must have been that the doses were smaller and not comparable to the doses of digitalis which he had given. If Dr. Levy had given larger doses of digitalis he would have obtained the effect quicker. Dr. Levy had established a proportional relation of the dosage of strophanthin and digitalis before he started, and it was interesting that the proportional doses did not produce proportional effects. It was also of great interest that following the administration of strophanthin there was so often a ventricular tachycardia, an unpleasant thing for the physician to observe in a patient as the result of medication. He thought the administration of strophanthin should be carried out only by those people working with it in hospitals until we knew exactly what effect it had upon the heart muscle. He had seen patients killed by strophanthin, and it was hard to say whether this specific effect of strophanthin in causing ventricular tachycardia might lead to ventricular fibrillation with resulting sudden death.

Dr. E. LIBMAN said that he had a few years ago tested out the intravenous use of strophanthus quite extensively. In only one case did it seem at all probable that the administration of the drug had caused a fatal termination. That patient, however, had a thrombus in the left auricle, and as was well known, sudden death might have occurred at any time, independent of any therapeutic method.

Dr. EGGLESTON emphasized the point brought out by Dr. Pardee, saying that the more he saw of the use of strophanthin in the present state of our knowledge the less he thought it ought to be used except under special circumstances. If adequate doses of digitalis were given by mouth the necessity for strophanthin intravenously would be largely obviated. On the second division of Bellevue Hospital a large number of patients who might have been considered as requiring strophanthin were successfully treated with large doses of digitalis by mouth. Dr. G. Canby Robinson had recently expressed the idea that one could largely do away with the use of strophanthin by resorting to adequate oral doses of digitalis. There had come to Dr. Eggleston's attention during the past few years several cases in and about New York in which death had followed the intravenous intramuscular use of strophanthin. These cases were under the care of men experienced in cardiac therapy, so that no blame could be placed on the technique or the selection of cases, but they rather indicated that the drug was not without serious drawbacks from the point of view of its dangers.

Dr. LEVY, in closing, said that he wished it clearly understood that he held no brief for strophanthin. The investigation was undertaken to ascertain facts concerning the clinical pharmacology of this glucoside. That the margin of safety between the toxic and therapeutic dose was small had been known for a long time. It was felt, however, that there was a need for a drug of the digitalis series for intravenous use, for there were times when urgent cardiac stimulation was required. Again there were patients who because of nausea and vomiting were unable to take digitalis by mouth. Individuals in coma, as for example, critically ill cases of pneumonia with auricular fibrillation might require cardiac support which could only be given by intravenous injection. Finally there were patients who did not respond to digitalis by mouth in whom satisfactory effects could be obtained by intravenous therapy. If the effects of digitalis could be obtained by giving it by mouth, then digitalis was the preparation of choice. This study was undertaken merely to ascertain the true value of strophanthin in the clinic based upon careful observation of its physiological action.

The Formation and Fate of Methemoglobin in Pneumococcus Septicemia.—Dr. WILLIAM S. STADIE made this presentation. He said that the pneumococcus changed hemoglobin into methemoglobin. Hence it seemed that methemoglobin formation might occur in pneumococcic infections and might be the cause of the cyanosis. However, a study of thirty-two cases of pneumonia had shown that there was frequently a diminution of the oxygen content of arterial blood and that the essential cause of cyanosis was the incomplete oxygenation of venous blood in passing through the lungs. To study the rôle of methemoglobin formation in pneumonia, a new method for the quantitative determination of methemoglobin in blood was devised. First, methemoglobin formation by chemicals was studied. It was found that the methemoglobin was always in the red blood cells, and while any proportion of the hemoglobin could be changed to methemoglobin the methemoglobin was eliminated from the blood stream with such great rapidity that it could not be found in the blood as early as fifteen minutes after the change of 40 to 50 per cent. of the hemoglobin to methemoglobin. Examination of the watery extracts of all the organs by means of the spectroscope showed that there was no storage of methemoglobin. The urine was always negative, and hence it was probable that the methemoglobin formed was rapidly destroyed. It was doubtful whether there was a catalytic production of methemoglobin from hemoglobin by the action of chemicals. The pneumococcus produced methemoglobin with great facility. The presence of the living organism was necessary. Filtrates and autolysates of pneumococci failed to change the hemoglobin. In rabbits the injection of pneumococcus produced a rapid diminution in the amount of hemoglobin present in the

blood. This diminution was due to methemoglobin formation; but in its production by chemicals this methemoglobin was rapidly destroyed, so that it could rarely be found in the blood of the infected animals, even though 40 to 50 per cent. of the hemoglobin had been so changed. It was only just antemortem that the methemoglobin could be found in the circulating blood. Here again examination of watery extracts of all the organs by means of the spectroscope was negative for methemoglobin, and the urine did not contain it. In occasional cases of lobar pneumonia, usually fatal ones, there occurred a sudden and rapid reduction of the amount of hemoglobin in the blood. This was due to a change of hemoglobin to methemoglobin, and these cases usually had very marked septicemia, from 1200 to 15,000 pneumococci per cubic centimeter of blood. However, repeated attempts by many investigators to find the changed pigment in the blood had failed, and from the above experimental work the following conclusion seemed to be justified. The nonoccurrence of methemoglobinemia in pneumonia, even when there was a marked fall in oxygen capacity, was, they believed, explainable by the results reported in this paper. Methemoglobin disappeared from the circulation with great rapidity, whether it was introduced by injection of methemoglobin or formed within the circulation by the action of chemicals or of pneumococci. Taking into consideration this fact, the ability of the pneumococcus to form methemoglobin, and the consistent failure to find it in the blood in the cyanosis of pneumonia, it appeared that the following statements represent the most probable explanation of what occurs: In the occasional cases of pneumonia which showed a decrease in the oxygen capacity of the blood, the decrease was probably due to a formation of methemoglobin. The latter was removed from the circulation, however, as rapidly as it was formed, so that it could seldom be detected, even qualitatively, and was probably never a cause of cyanosis.

The Treatment of Empyema Caused by Pneumococci.—Dr. HOMER F. SWIFT read this paper, in which he stated that the great prevalence of empyema in army cantonments during the past three years had resulted in certain new principles being widely accepted for the treatment of suppurative pleurisy. It was desirable to study the differences between streptococcus empyema and that following lobar pneumonia. These differences were not considered as often as they might be. In the streptococcus cases the exudative pleurisy was frequently present early in the disease, and consequently the patient had marked general depression and but little fibrinous exudate on the surfaec of the pleura. Wide opening in the chest wall led to collapse of the lung, shifting of the mediastinal viscera, and sometimes to compression of the opposite lung. The picture of shock was increased and danger of bacteriemia more marked than if operation was delayed until later. In pneumococcus empyema, on the other hand, the suppurative exudate was not usually found until the acute infection had been present several days and often not until after the time of the crisis. Extensive pleural thickening was usually present. Ordinarily, therefore, the various conditions that caused thoracotomy to be delayed in streptococcus empyema were not operative in post-lobar pneumonia empyema. Among 770 lobar pneumonia patients, in 41 there had been a diagnosis of empyema during life, or found at autopsy. In four it was one of several general complications; these patients were not operated upon, as they represented a type in which no form of therapy was of avail. The distribution by types of pneumococci from which the patient was suffering showed that about 8 per cent. of untreated Type I cases, 7.4 per cent. of treated Type I and the same per cent. of treated Group IV cases developed this complication. There was, therefore, no statistical evidence in their patients that serum treatment predisposed to the development of this complication. Among 37 patients in whom the diagnosis was made during life and operation was performed only three died. In all three the operation was performed after the twentieth day following the onset of the pneumonia. In all the patients in whom the operation was performed early, that was, from the third to the eighteenth day following the onset of the pneumonia, recovery was the rule. No advantage could be discovered for delaying operation by repeated aspiration of the fluid that contained pneumococci. They, therefore, felt that the fluid obtained by exploratory puncture—and this was the only certain diagnostic procedure—should be examined both microscopically and culturally. If pneumococci were found by both methods, it was safe to make a diagnosis of suppurative pleurisy and to operate at once, provided the patient's condition was not a contraindication to a general operation.

Dr. B. S. OPPENHEIMER said that he had not seen so many cases of empyema this winter as Dr. Swift reported, but those he had been able to follow had all done well on the policy of waiting until the patient was quite recovered from the pneumonia and then operating promptly. Some of these had been pneumococcus cases. He asked Dr. Swift to analyze his series to show the relation of the operation to the course of the pneumonia.

Dr. LIBMAN said that he did not suppose that Dr. Swift meant that one should operate if fluid was only slightly turbid, and contained bacteria. He drew attention to cases in which there were present two effusions adjacent to each other—the one being definitely purulent, and the other one being only slightly or not at all turbid. He showed how it was possible in some cases to suspect that there was a double effusion. Sometimes the effusion secondary to the distinctly purulent exudate contained a small number of bacteria, and the focus would clear up after the purulent exudation was drained. In cases of tuberculosis, when there were two sacculations present, both of them usually showed clear fluid. In cases of infection of the lung, particularly with pus formation, the pleural fluid might contain a few bacteria, and these bacteria might not be visible.

Dr. SWIFT, in closing, said his object in making this presentation was to point out that it was necessary to study the patient and the type of infecting organism and not to make any fixed rule as to what we should do simply because a diagnosis of empyema had been made. He endeavored to point out the difference between the streptococcus and the ordinary empyema following lobar pneumonia and that the condition of the patient must be considered. If the patient was very ill and clear fluid was found it might be better to wait until the general condition of the patient had improved. However, the presence of pus often kept up the general symptoms which we all recognized as toxic. In patients who were febrile a drop in the temperature and pulse had been observed soon after operation, so that he felt that the sooner free drainage was established the sooner the symptoms passed off. The number of cases was too small to give the comparative rates of recovery in the cases operated upon early and late, but it seemed that the earlier drainage was instituted after the fluid collected the better were the results. One should make cultures of the fluid, as well as examine spreads. In most cases the bacteria were so numerous that one was not long in doubt as to the organism. They had not studied the relation between the date of the empyema and the day of the crisis, but in general the empyema was discovered after the time of the crisis. When the diagnosis of an empyema with pneumococcus infection was made it was time to operate.

Normal Maternity in a Myxedematous Woman.—Adam states that while myxedematous women not infrequently conceive, labor and its sequelæ are rarely normal. The woman in question was thirty-four, and had borne a child. There was no endemic goiter in the neighborhood. The first child was born thirteen months after marriage and was a forceps delivery, ending in still birth. Patient went seven years before another conception, her menses having been normal throughout. She was a typical myxedematous subject, the thyroid gland being extremely small. Intelligence was almost normal. The pelvis showed general contraction. The second labor and the resulting infant were alike normal, labor having been without assistance of any kind. The weight was a little under 3,000 grams. There was no mention of thyroid treatment during gestation, and doubtless the patient was not seen long before labor. —*Le Progrès Médical.*

Miscellany.

A Gypsy Girl as Surgeon's Aid.—The highly developed powers of observation and retentive memories of the illiterate are well known. Negroes usually have remarkable memories. Indians are able to read records in the forests and streams and along prairie trails and wave-washed beaches, undecipherable and often not even visible to the white man.

In Albania the same faculties are highly developed among the Gypsies, who are the pariahs of that land, both Mohammedans and Christians looking down upon them, and absolutely refusing all intercourse with them except on the plane of servants.

A notable instance is afforded in the case of "Mina," now a regularly installed member of the personnel at the American Red Cross Hospital at Tirana. When first introduced to the Red Cross, Mina was selling wood in the streets for a living. She was about 22, and with none of the beauty that sometimes characterizes the Gypsy women. Her face was full of character and intelligence, however, and when she applied to the hospital for work, a place was made for her among the other Gypsy servants.

From the first she exhibited traits not always to be found among her tribe. She was trustworthy, neat and energetic. Nothing pleased her better than to be allowed as a special favor to sterilize the surgical instruments. She would work indefatigably, scouring and scrubbing and fumigating the premises in the hope of being rewarded with this coveted duty.

Her intelligence and scrupulous cleanliness attracted the attention of the doctors, and she was promoted to the care of the operating room. In due time it became apparent that a sense of order was another of Mina's natural virtues. It was noticed that whenever she received a set of instruments to sterilize they were invariably returned to their proper cabinet in the exact order in which they had been originally laid out for the operation. Moreover, it was not long before Mina, though unable to speak or write a word of English, could grasp just what set of instruments would be required as soon as she was made aware of the nature of the operation to be performed. It was then that her accolade was received. To Mina, the unlettered Gypsy, was given full charge of the operating room. Its proper cleaning, disinfecting, sterilization of apparatus, and laying out of equipment were turned over to her, and nobly she rose to the occasion. Not another servant would she allow to cross the threshold.

As soon as the room was vacated this faithful Gypsy was busy with her mops and disinfectants, making it immaculate again. To-day she is regarded as one of the most indispensable members of the Red Cross Hospital personnel. Her memory never fails, nor is there ever the slightest inaccuracy in the laying out of a set of instruments for the doctors and nurses. Untutored though she is, her powers of observation have proved to be a guide quite as reliable as the most carefully thought-out printed instructions for the enlightenment of the better educated.

The "Man-Insect-Bacterium" Complex.—Ferrière, an entomologist of Berne, is responsible for this expression, which calls attention to a state of affairs already too well known in pathology. Of diseases in which the insect is the sole means of propagation may be mentioned typhus, recurrent fever, trench fever, yellow fever, pappataci fever, plague, sleeping sickness, filariasis, etc. Again insects play a certain rôle in the diffusion of typhoid, dysentery, cholera, and tuberculosis. One might add that the insect also plays a rôle in the diffusion of wound sepsis. During the Spanish-American war the Americans lost over 5,000 soldiers from insect transmission. In regard to individual insects the louse since 1914 has been regarded as a menace. The flea has been recognized as the carrier of plague since the recrudescence of the malady in Turkey many years ago. Two main genera of fleas are now accused of transmitting the disease—the Indian or *Xenopsylla* and the European or *Ceratophyllus*. Both are rat fleas. The wholesale destruction of rats causes the fleas to seek other hosts and the crusade against fleas makes it imperative to draw no lines but proceed against all species. In addition to the general use of insecticides it is necessary to clean out all dusty corners and spaces between boards, to take up carpets, etc., for in such localities eggs and larvæ are to be found. Next in order comes the fly problem (so far as France is concerned, although in many localities the mosquito takes precedence). There is hardly a germ disease that the fly could not conceivably transmit, even including anthrax; germs have been encountered in the ova of the fly and the insect not only is covered with germ life but swallows and extrudes the latter. The late war has brought home the existence of the plague of flies, for the diffusion of the insect is universally favored under war conditions. The main strongholds for the fly plague are dunghills, kitchen refuse heaps, and latrines, and it is not difficult to proceed against these institutions. —*La Presse Médicale.*

Wanted a Fat Man.—According to *The Modern Hospital,* the superintendent of a certain hospital, upon tracing down the apparently unwarranted criticisms of his institution, which he knew to be first class with regard to professional and nursing services, food, and other important elements of a well-equipped hospital, found the source of discontent at the very portals. "Quick" and "efficient" attendants at the information desk and switchboard were the trouble makers. Now the superintendent is looking for "a big good-natured man"—two, if necessary,—"men who will wear well, who can smile, and who will make people good-natured in spite of themselves." It takes a fat man, he now thinks, to accomplish that feat.

"Glass Eyes While You Wait."—The London *Daily Mail* announces that ex-soldiers may now obtain in London perfect replicas in glass of their lost orbits "while they wait." The patient sits beside the "artist" who, with glass tubes and blow lamps, faithfully copies in glass "the exact color of the white, the small red veins and the delicate blends of color in the iris." In one of the large London "studios" it is claimed that perfectly matched artificial eyes can be made in twenty minutes.

DESCRIPTIVE PSYCHOLOGY AND MEDICINE.

BY CHARLES L. DANA, M.D.,
NEW YORK.
PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE.

PSYCHOLOGY is a science that has been studied (not without acrimony) from many angles; and in recent times applied in many directions. We have now books on physiological, abnormal, social, vocational and behavioristic psychology and others. Some technical knowledge of psychology is very useful for the understanading and management of the patient and his disease, and in certain lines of practice such knowledge is imperative; yet I find it rather generally lacking. Perhaps for this reason various psychological cults, which appeal to the imagination find easy absorption here.

Besides this, a good deal of confusion in description, classification, and interpretation has resulted from the differences among writers in their vocabulary and their standpoint. Hence I make no excuse for giving a brief account of some of the different fields of psychological work, with their relative values to the physician.

I especially wish to present certain elementary facts and definitions in the science. If these are not final or even are not all correct, they at least represent the situation as fairly and as authoritatively as I have found it possible.

Psychology is the science of the mind and it is essentially one science. For while there is an abnormal psychology, a physiological psychology, a descriptive psychology, etc., these all deal with the mechanisms and laws of mental action. Whether the mind is abnormal or diseased or sound, the scientific data of psychology apply just the same. It is all a biological process, to use a word dearly loved by the psychological intelligentsia. The mind has a kind of anatomy or structure of its own *i.e.* its activity is accompanied with and dependent on the production of certain definite states and processes, such as sensation, perception, reasoning, etc. When the mind functions it does so through the medium of these states, and in accordance with certain laws. The mind cannot act without the formation of ideas, the development of feelings, etc., or without the processes of association, memory, etc. Its activities may be modified, however, and even initiated by the conditions of the nervous system and by the play upon it of the physiological processes of other organs, such as the blood, the internal secretions, and the nutritive and eliminative organs.

We may speak, therefore, of a descriptive psychology which defines and describes; a dynamic psychology which tells of forces and laws; and a physiological psychology which studies the modification and control of mental action through physiological (and pathological) changes. These are all only different methods of attack upon the general problem.

The application of psychology to education and industrial life takes us into the fields of practical activities and human conduct. In abnormal and medical psychology we also apply the terms, methods, and data obtained by the three group-methods mentioned above. The behaviorists deal with conduct, and do not call their science psychology.

Dynamic psychology is a science based on a study of the forces and their interactions which lead to mental activities and human conduct. Dynamic psychology attempts to explain the phenomena of the mind by finding the causes and establishing the laws of mental action. It cannot yet prove the existence of such forces and laws because they are not in the field of observation. But the laws are *conceived* to be such as will explain the phenomena, and, being applied, do seem to explain them. Hence dynamic may also be called a conceptual psychology. (B. Hart.)

Dynamic psychology gathers data also by observation, and groups and classifies them. But its interpretation of the laws of mental action is obtained by reasoning processes, and is worked out without reference to physical phenomena or to physiology. It does not "mix up brain cells and mental acts." Its explanatory laws correspond to certain of our conceptions of physical laws such as that of gravitation, of the nature of the atom, and of the ether. Any given state of mind occurs because of the methodical working of supposed mental forces, and in accordance with certain conceived of laws.

These underlying working forces have been called the "drives," the *élan vital*, the libido, the instincts, etc. As to the nature and unity of this force there is still disagreement. But it seems to be established that mental activity and human conduct have several different "driving" forces. At one time the sexual instinct, *i.e.* the instinct for the preservation of the race, was assumed to be the main driver; then there has been added the instinct of self-assertion and advancement; then that of self-preservation; that for herding together (the group instinct); that for religious observance; and that for social betterment.

Associated with these and forming their effective sides, there are described the emotions, of love, desire, vanity, and self-distrust; of anger and fear, and of religious exaltation and devotion. There may be also something in the nature of a "pull" which incites to mental action and human conduct.

This is shown in the influence of an ideal towards which one strives.

These instinctive forces work both consciously and unconsciously and one may be quite conscious of the emotion or of a driving force and not quite aware of the kind of compelling instinct that arouses it.

It is to secure the proper interpretation of these forces that there have developed the methods of psychological analysis. And efforts have been made to explain in a mechanistic way those morbid mental states called the psychoses and psychoneuroses. Some explain these on the basis of disturbances in the "driving" force of the sexual instinct; others on the basis of a compelling sense of inferiority; others on the dominance of fear, and on disturbances of and antagonisms to the herding instinct. All these "drives" may be modified by abnormalities in mental make-up and development, as for example when the adult life continues to be a juvenile one. These various instinctive urges, when thwarted or deviated, are assumed to lead to emotional perturbations and psychoses. There have been conceived various laws or mechanisms of mental action which go under the names of *dissociations, complexes, conflicts,* and *repressions.* It is believed that the minds shows *resistances* and has a kind of *censorship.* There is an activity of the mind called *projection* by which it is assumed that the individual's complex is passed on to another person. *Symbolism, phantasy, day-dreaming,* and subconscious wishes, defenses, and attempts at readjustment are further agencies in the psychological mechanism. The conceptions of the wish, of dissociation, and of conflict are very important in explaining normal and abnormal phenomena. The existence of a well-organized *subconsciousness* that acts on the conscious is assumed, or perhaps demonstrated.

The definitions and details belonging to this phase of psychological science must be sought in the works of Freud, Jung, Adler, Trotter, and other interpreters.

This conceptual psychology is plainly a sound method of scientific attack. It has worked out various hypothetical laws which may be wholly and are certainly partly true. In fact to a large extent, this psychology tells us in sicentific or technical language what students of human nature and ordinary psychology already know. Since the beginning of neurology at least, we have known for example that a woman's headaches and hysteria were her methods of defense and self-exploitation. Its essential merit has been to show most emphatically the high organization, influence, and importance of the subconscious activities.

However, the laws of a conceptual psychology do not work in the production of mental phenomena, without some correlated activity of the brain and body. One can not explain morbid mental phenomena by conceptual phychology alone. There is always some defect of structure or function. Healthy brains have no delusions or obsessions, no morbid fears, abulias, or melancholias. No matter how deeply fixed is the subconscious disturbance, the delusions of general paresis in a man with a luetic encephalitis are not due to activities and forces altogether psychological. When a person has an injury of his angular gyrus or parietal lobe and has alexia, or agnosia, this psychical state is not due to complexes or repressions or any purely conceptually conceived mental law. When a man gets a blow on the head and has a dissociation leading to a hysterical mental state, there are physical changes as well as mental. Physical changes, toxemias, infections ,internal secretions may lead directly to association disturbances and directly to consequent morbild mental phenomena.

Strong emotions, such as anger and fear, arouse definite physical changes in the body which in turn contribute to the content of the mind and its direction of bodily action. Such emotions show themselves largely through the sympathetic nervous system. On the other hand, morbid states of the sympathetic act as direct exciting forces in producing mental states. A study of these facts may not be a part of a conceptual psychology, but it is a part of physiological psychology.

We may say that mental phenomena and bodily phenomena are both biological activities, representing two different phases of life activity, each to be studied separately. They may indeed be studied separately, but in medicine it is necessary to know their relations and interactions in order to enable us fully to recognize the causes and cure of diseases. Nothing is more important now than to show these relationships. Mental defects and disturbances may be relieved by interpreting to the patient the misdeeds of the mind, the misuse of its resources, its misfits, and repressions and conflicts, but the fact that a defect in the body is often more fundamentally the cause of badly worked machinery of the mind, is quite absolutely established to-day.

In connection with the study of the psychology of trauma the presentation of the relationship between injuries to the central nervous system and mental states, has been discussed by me in an article on the Somatic Origin of the Psychoneuroses (*Journal of the American Med. Assoc.*, May, 1920). Basing my statements on experiments made during the war on the effect of direct, indirect, and remote concussion, I showed what is at times the relationship of physical cause and psychical effect. In other words, it seemed proved by experiment, that the production by physical means of certain definite molecular or wave changes in the arrangements of the brain structure may cause definite morbid or special normal mental states.

A table in which the matter is presented schematically, is given here, showing the results of tremendous detonations on animals and men in zones at definitely removed distances, there being no element of fear:

X is the center of detonating force; Zone A, of a man receiving a direct concussion; Zone B, of indirect concussion; Zone C, of indirect concussion by high frequency waves.

The patient in Zone A is killed. The patient in B or C receives and feels:

1. Concussion waves on the brain; and hears
2. The detonation.
3. Physical changes occur in the nervous system due to concussion with gross, or fine, or molecular waves.
4. Emotion follows, *e.g.* of fear, leading to Nos. 6 and 7.

5. Subconscious desires, defense activities, adjustment activities, leading to No. 7.

6. Organic or biochemical disturbances in the nervous system (toxic or endocrinic, leading to No. 7.

7. Psychoneurotic phenomena.

Under the head of physiological psychology then we study all the physical and physiological changes which excite or lead to changes in the mental state. The action of poisons, autotoxemias, and internal secretory disturbances, form one line of inquiry. Others are the effect of changes in the sympathetic and autonomic nervous systems; the effect of physical injury and disease; the modification of physiological activities of the viscera through the forces of mental action; the study of reflexes, and particularly of that phenomenon known as "the conditioned reflex" by which many abnormal mental and nervous phenomena are explained.

We have then a static, a dynamic, and a physiological psychology. In medical practice psychology must include some knowledge of all three groups and even needs an acquaintance with applied or vocational psychology, and psychometric methods.

Of these three fields of psychology, I shall go into some detail only as regards one, viz., descriptive or static psychology. This is the elementary and introductory phase. A knowledge of it is necessary in order to understand the vocabulary of the sicence. I am presenting it, however, largely in the form of definitions which are based on consultation of standard works by James, Marshall, Warren, Baldwin, Pilsbury, McDougall, Woodworth, and I have used as far as it goes the report of the committee on Definitions of the American Psychological Association. The works of Morton Prince, Janet, and others have been consulted, and I have had the personal advice on some points from Prof. J. McK. Cattell and Prof. Woodworth.

Consciousness is the name given to that quality of the mental state through which a person becomes aware of himself as one distinguished from the rest of the world. It is the distinctive characteristic of mental life in actual process. This conscious state, or state of "awareness," constantly changes, and each state represents but a moment of time. It accompanies all our volitional acts, but there is a large amount of mental activity that goes on unconsciously.*

Consciousness has its focus where awareness is most marked, and its marginal part where awareness is more dim. And consciousness can exist in varying degrees of clearness in connection with more than one mental process. Thus a person can play the piano, reading the notes of the music, and talk or think on another subject. In behavioristic psychology the existence or at least the study of consciousness is ignored.

Subconsciousness: Mental phenomena which in degree of vividness or clearness are below the threshold of distinct consciousness are said to be subconscious. Consciousness and unconsciousness are terms used by some writers.

The subconscious "represents a detached phase of mental life of which the individual is not directly aware. It is a subordinate or co-ordinate consciousness," (Com. A. P. A.) and is considered by one school to be very highly organized and detached to the point of being called anthropomorphic, *i.e.* a separate mind within the conscious mind.

Unconscious is a term often used to characterize reflex and autonomic activity; it is also used to characterize certain modes of instinctive activity, somnambulism, and perfectly formed habits. (Com. A. P. A.)

Sensation is the simplest unit of human consciousness. All afferent nerve impulses which reach consciousness arouse sensation. A pure sensation has no associated images. We have a sensation of a light, a color, a sound but it connotes nothing. When it does associate itself with previous experiences, we get a percept.

Perception: On seeing or feeling an object we instantly associate the sensation with previously recorded impressions. In doing this we perform the act of perceiving, and the result is called a *percept.* Thus we see a round, yellow object, and immediately associate it with previous experiences, which tell us that it is rather rough to touch and of peculiar odor and taste, and we perceive that it is an orange. Thus the process of perception is the grouping of a sensation with previously recorded impressions, the result being that we recognize a particular object which, in perception, is *always outside of us in space.*

Some psychologists put their views in physiological terms, and define perceptions as mental states in which many nerve impulses coming in separately from external receptors are combined to form a single complex experience.

Ideation: An *idea* is the reproduction, with a more or less adequate image, of an object that is not present to the senses. A *percept,* on the other hand, is a representation in the mind of an object that is present before us in space. We perceive the orange; we have an idea of what an orange is. In the building up of an idea we group together or associate our various sensory and perceptive experiences until we finally get this special notion or idea, which comes to our mind without having the object itself before us.

A *concept* is an abstract or universal idea, recognized apart from any special or particular qualities; the word is used with various meanings, however.

By associating various ideas together in a certain regular way so that there comes from them something new, we reach a judgment, and this process of associating ideas to an effective end is called *reasoning.*

Reasoning, then, is a process which leads to some new fact and differs from a casual association of ideas, such as occurs in revery (autistic thinking), or in the ordinary play of association by suggestion, as when a gray horse suggests the presence of a red-haired girl, or when the smell of gas suggests a leak in the pipe. Sometimes in the association of ideas in speech we proceed from one inference to another, or one thing is suggested by another, until we reach a point in the discussion which may be simply the climax of a story, or the exposition of a point of view, or description of some past event. When the associations thus lead to some definite point or idea, we speak of it as the "goal idea," and

*"Consciousness is not equivalent to mind, self, soul, or psyche, but is characteristic of them." Com. A. Psyche Assn.

in most rational speech or description there is this *goal idea.*

Judgments are conclusions reached by the processes of association. These may be elaborate and conscious, or simple and very largely subconscious processes. Thus many conclusions and opinions develop in the mind almost unconsciously or through slight suggestion.

Memory and Orientation: The activities of the mind are dependent on the power it possesses to retain and revive impressions; that is to say, its power to remember and recollect. This faculty of the psychic cells is called *memory.* It means that all stimuli sent to the brain make some kind of impression on the central nerve-tissue, which impression can be revived at future times by other suggestions and stimuli. This process of record and revival is a form of association, and memory revival means the re-establishing of an association (Marshall). Memory forms part in most conscious psychic life. The mind cannot work without its constant help, though the memory may be good, and yet the mind works badly. The feeling of identity or personality is dependent on memory. Memory is usually divided into the power of learning or memorizing and the power of reviving or recollecting.

The knowledge of our relation to the external world, our appreciation of time and space—in other words, our *sense of orientation*—is dependent on the memory.

Cognition is association by similarity.

Recognition is association by contiguity.

There is no sharp line between the two.

Imagination is the associative combination of concepts and percepts into new ideas.

Instinct is the faculty of acting in such a way as to produce certain ends, without foresight of the ends, and without previous education in the performance.—(James.)

Put in another way, it is that form of behavior which involves a series of consecutive reflexes which are dependent on inherited structure and lead to a purposeful end. They may be grouped mainly as reproductive, defensive, aggressive, and social or herd instincts. Some writers enumerate as many as twenty-six. Instincts are built up by evolution in the race and transmitted by inheritance; they develop at various periods of life.

The expression of instinct is usually associated with a percept or idea, and an emotion; and emotion is said to be the affective phase of instinct. The instinctive feeling is automatic, but the conduct and feeling that follow are modified often by training and experience or by artificial motives. So that instructive acts may finally represent the consolidation of habit and instinct.

Feeling or *affect* is not a separate function of the mind, but is a quality of the different mental states; that is to say, every mental state is accompanied by some kind of feeling, either pleasurable or painful, or has some quality that can be regarded as indifference. The affect may not necessarily be distinctly disagreeable, but may pertain to some subjective sensation, like hunger or thirst, or some simple desire of action. In all cases feeling only qualifies or gives a certain character to the mental state.—(Marshall.)

Other psychologists say that *feeling* or *affect* is something only associated with a sensation. It is pleasurable, painful, or indifferent. Certain pleasurable and painful feelings have their seat in the thalamus.

Emotion is an intenser tone of feeling which is usually attached to a percept, idea, or concept in which our primary impulses are opposed or gratified. One perceives the beloved one and feels the emotion of joy. One sees a snake and feels a fear of personal injury.

It may not, however, be exactly or entirely an instinct which is thus satisfied or opposed in the arousal of emotion. There is in the human being a variously named mental force, pressing us on. It is called the *élan vital,* the libido, the instinct, or a "primary impulse, or sentiment" (Shrand). This is derived from instinct, in part, in part from experience, in part it is the urge of living tissue. It is when this force is encouraged or checked that we get emotions. Every primary impulse when opposed arouses anger; when satisfied, joy.

But besides the emotions associated with primary impulses and definite conscious states, there are conditions of painful emotion, *e.g.* in melancholia, not associated always with any conscious and not always with subconscious ideas. There is also the pure causeless emotional exaltation of mania. Here emotion is due to some somatic state that inhibits or stimulates neural activity. These are physiological or pathological emotions.

The list of emotions includes surprise, love, hate, desire, pleasure, displeasure, fear, anger, sorrow, disgust, wonder; and combinations of these also appear.

The emotions are less useful and important as the mind becomes more cultivated and man more civilized; and if civilization goes on without a corresponding control and inhibition of emotions the field for psychoneuroses increases. Emotional indulgence is always associated with physical and glandular and circulatory changes, so that somatic injury can be induced by emotional excess.

Esthetic emotion in its milder degrees is really only a feeling such as is aroused by beautiful color combinations, or the simpler musical sounds. In minds highly cultivated or endowed to appreciate the beautiful, there is when a beautiful thing is presented a percept or a recognition of what some call "significant form." This arouses an esthetic emotion which is associated with the intellectual act of recognition. What primary impulse is favored or opposed here can only be surmised. It differs in the different arts. Often, as in painting, it is possible to have pleasurable feeling at the sight of a picture because it arouses ideas related to our instinct of love, or hate, or social life. In so far as the picture suggests only significant form or a harmonious relation the result is simply esthetic feeling—a vague sensory state. In music, for example, the realization of a significant form in the music is a process of perception, and the hearer may feel the emotion of joy at recognizing this musical form. In poetry the presence of a significant form, *i.e.* the rhythm and rhyme, and assonance, or sonority, arouses esthetic feeling. The ideas of the poem may arouse instinctive feeling or emotion. Thus in poetry we

may have both feeling and a wide range of emotion, which in great poetry is strengthened by appeal to our ideals and by its revelations of new concepts tinged with emotions.

The physical facial expression of emotion has a center in the thalamus, at least to a degree. Certain painful and pleasurable cutaneous sensations have also the seat in the thalamus.

Passion is an intense emotion of short duration; and mood a prolonged but moderate emotion.

Temperament is the instinctive, inherent tendency of the individual to react to particular conditions.—(Ash.)

Character in its best sense is the inhibiting or directing superstructure which is built upon by temperament through experience and habit. It should be the steadying influence upon morbid temperaments.

Personality is the resultant of combining temperament and character. It represents the total response, instinctive and acquired, of the person, to the influences and conditions about him and in him.

The *volition* or will is technically the conscious realization of the strongest and therefore deciding feeling. It is usually accompanied by a motor act, although a person after consideration may reach a conclusion and not act on it until later. The process of volition may comprehend both the formation of a definite judgment or preference and the expression of it in action. We see an apple and a stone. The idea after comparison comes to us that the apple is more desirable than the stone. The desire for the apple and the intellectual and emotional preference for it over the stone sets to work the impulse to take it, and a volitional act is performed.

The volition function is not therefore simply or only voluntary action, but includes the whole conscious process that led to this act. In this process we are made to feel that we have a power within us that can reach any of several judgments and lead us to any one of several choices. This leads us to believe we have a free will and are responsible for our acts; and society holds men responsible on the basis of this view. We accept it as long as we feel that there is the ordinarily free play of association and inhibition, so that the decision or choice comes about without any artificial or abnormal interference.

When an act is done without conscious preference or desire, or in response to an impulse coming upon one from subconsciousness, it is an involuntary or *impulsive* act. Acts which are done under the influence of a conscious feeling like an obsession are *compulsions*. Acts which are the expression and result of habit and which are done without our having any memorable consciousness of them are called automatic. Many acts are brought about by imitation and suggestion, and these are often done with so little conscious volition that they belong almost to involuntary or complicated reflex actions.

53 West Fifty-third Street.

*"Emotions are biological psychophysiological instincts, or instructive reactions later organized into systems with ideas of objects." (Prince)

"An emotion is an hereditary 'pattern-reaction' involving profound changes in the bodily mechanism as a whole, but particularly in the visceral and glandular systems." (Watson)

PARALLEL BETWEEN DREAMS AND PSYCHOSES.

By GEORGE PORTER BOULDEN, M.D.,

DONGAN HILLS, STATEN ISLAND.

SENIOR PHYSICIAN, CENTRAL ISLIP STATE HOSPITAL; FORMERLY ASSISTANT PHYSICIAN, MANHATTAN STATE HOSPITAL AND SENIOR PHYSICIAN (ASSISTANT SUPERINTENDENT) NEW YORK CITY CHILDREN'S HOSPITAL FOR MENTAL DEFECTIVES, RANDALLS ISLAND.

"Such stuff as dreams are made of."

—Shakespeare.

IN connection with a consideration of certain features of dreams some conjectures and inferences are here offered which, while somewhat immature, it is hoped will be found of interest. At least the subject is an interesting one; for, "if we understand the underlying, the 'hidden,' the basic meaning, motives and dynamic sources of dreams we will find ourselves in a fair way to understand the universal man."

A dogmatic method of statement may appear to have been used, but the only aim has been conciseness. The suggestion of applying the ideas presented to a partial explanation of the clinical manifestations of certain mental conditions is obviously rather vague and needs further elucidation after more careful study. Dr. Kirby has pointed out that "the idea that dreams occur when some areas of the cortex are awake and others asleep has been advanced by many observers, having been mentioned by Benjámin Rush in his book on mental disorders in 1812; that the French neurologists have also used the same hypothesis to explain some of the phenomena of hysteria and that Jung emphasizes certain similarities between a person dreaming and cases of dementia praecox." Therefore, originality is not claimed except in bringing together some suggestive ideas which have apparently been in the minds of numerous writers of authority, to whom appropriate credit is meant to be given. And here I must assume full culpability if I have misinterpreted them.

The purely theoretical character of the matter under consideration makes it, at least at this time, impracticable to present clinical evidence pointing to probability, especially because, as stated later on, the obscure elaborative changes which are assumed to be carrying mental development to still higher levels are likely to be always just beyond material recognition. "Beings advance in time, treading as it were, upon a carpet which they weave with whatever colors and textures they wish but they are ever rolling this carpet up behind them and carrying it with them."*

It follows that no intimation is intended that these intellectual areas or levels can now be anatomically defined nor could one be sure that they ever will be. If their existence is accepted it will probably be on theoretical grounds.

The comparatively simple nervous system of the early vertebrates has been retained as the sympathetic or vegetative system in man and practically continues to do what it did for them. As the animal, in the course of evolution, rose higher and higher in the scale, new and more elaborate stations appeared—the spinal cord, the medulla, the pons, the midbrain and thalamus, the cortex and its different layers. These are big jumps and by

no means list all the intermediate steps. But as these elaborations were added one to another, summarized representations of each lower step appeared in the higher; and it is now believed that there is a representation of the vegetative system in the cortex and most probably of each subsequent station in the progressive development of the higher levels.[5] "The change in direction of mental processes is . . . due to a shifting or advance of the focus of consciousness from one point to another . . .."[6] It is probably not meant that communication was simply established and function turned over to the later and higher developed areas; but, by interruptions, a sublimated, synoptical shadow of the essential workings of the lower levels is transmittted, ever becoming more remote and attenuated as level rises upon level, but the connection never entirely disappearing, and refinement of control becoming more manifest.

It is possible that, were impressions received directly by the cortex without the attenuation which takes place in the various synapses, they would be so strong as to endanger the more delicately moulded cells of the cortex; or, to speak figuratively, their clamor for audience would be so loud as to be deafening.

The propinquity of intercommunication is greater between the levels of the medulla and pons and cortex, as seen in the ability consciously to control or inhibit many motor impulses reflexly excited in the medullary and pontine ganglia; and, as we go higher in the evolution or individual development, the relationship may be ever closer but still distinct. Many of the bonds of association between the steps can be, and others probably will some day be, demonstrated; but the latest elaborations, as such, will likely be too fine for differentation by any means which man will ever possess.

"Veil upon veil shall lift, but there will remain
Veil upon veil behind."[4]

We know that much functional development, probably dependent on obscure structural changes, takes place after birth in the speech mechanism, the cells capable of this development being present but untrained at birth, and that areas for auditory speech memories and later visual speech memories become specialized, this further differentiation taking place when the child learns to talk, and to write, and again when music or a new language is learned;[5] and as each of the successive stages of life, from infancy to full maturity, is reached, probably the multiplicity of experiences and the necessity for the storage of their memories require transfer of conscious command higher and higher. These represent to-day the different levels the individual has passed through since birth. Some day some of them may represent a part of his birth endowment. From a consideration of the primary speech mechanism and the transfer of its control later to the cortex and still later to special speeech areas in the cortex, we are reasonably certain that, after birth, many acquisitions require a transfer, from the medullary reflexes to the cortical areas, of the responsibilities of conscious existence. We may infer that elaboration does not stop here but that differentiation goes on as need arises and that at least several levels of consciousness or specialized areas, more or less distinct but related, are set up in the cortex itself from childhoood to maturity.

We may be willing to admit that this advance of the "focus of consciousness" is at least partially accepted as a fact. And regarding this as partially so we may carry the inference further. Our hearts beat, our lungs respire and our other viscera perform their vital functions; but at such a distance are they, communicatively, from the cortex that, in health, consciousness interprets the attenuated signals received from the vegetative ganglia controlling them only as assurances that everything is going well, thus conveying the sense of general well-being, of bodily satisfaction. Meyer Solomon says: "In viewing mental tendencies and activities from this [his] standpoint we must include not only our infantile (superimposed upon which are our childhood and adult) lives, but also our phylogenetic and ontogenetic—our evolutionary—life history"; and "if we would say that for every psychic fact or state there is a logical and efficient antecedent causative mental state, then we cannot say that that mental state must have occurred in the present life-history of the individual."[1]

There may be a question whether the brain of a child, which we know is roughly moulded in the parental matrix, does not at times reproduce from dimly outlined negatives faint pictures of parental experiences. These may explain the belief that some people have, that they can remember a previous existence, a former incarnation. But, if so, these were imprinted by notably understandable, pre-natal events of more than striking importance, and the individual impression at best is a feeble one.

We almost know that the elaborations above referred to are taking place, and, because of our inability to perceive them, usually consider them as functional differentiations. They doubtless represent to-day the beginning of changes which will be microscopically or chemically recognizable when they shall have progressed further, as they will, in their development. The assumption is that Man will not stop at the intellectual level he has now attained.

A great deal has been written about dreams and their symbolism upon which it is not necessary to dwell, but that dreams have an overshadowing significance is probably admitted, and it may be that a study of their significance will eventually furnish a working hypothesis for the explanation of the mechanism of some mental conditions now incompletely understood. Dreams may be looked upon as a very transient psychotic state—"they border on the pathological."[6] The parallel may be extended. Dreams are fairly accessible clinical material and from their study theories which may explain some psychotic conditions may be evolved; not so much, I think, if symbolism is considered as from the point of view that psychoses represent definite (temporary or progressive) changes in the different cells or areas where is the seat of consciousness and intelligence.

We know that individual cells of the human body are capable of independent existence when the proper conditions are present.[7] Experiments have shown that some human tissue cells live and multiply experimentally in artificial media even when the body from which they were removed has un-

dergone the extreme change of death. We may well assume, then, that when the brain, and hence the body, is in the state which we recognize as sleep it is possible that all the cells of the brain having to do with consciousness may not react in sleep—may not be equally tired and go to sleep—at one time, except under very favorable circumstances where the balance of effort producing the reaction has been very exact. The environmental aspect, so far as independent functioning is concerned, has not in this case been changed as in death.

It may be, therefore, that, in sleep, the whole brain is not always unconscious. When it is, there are no dreams. When it is not, the level which is awake is more or less active and uncontrolled by associations with other levels. "Sleep, varying in degree, is accompanied by a certain degree of consciousness."[1] The experiences and memories of the level or area that is awake are the ones which are most apt to appear in the field of partial consciousness, and even if suggested by somatic stimuli or by sensory impressions received from the environment are apt to be interpreted or distorted by the ideas and memories or experiences peculiar to the level that is awake. "The state of consciousness during sleep, biologically ordained, employs, during its activity, the mental material at hand—the past mental content plus any somatic or external stimuli."[1] In full consciousness the entire brain and all its associations must be awake.

The dreams which would appear in consciousness as memories of the vegetative level are in character too remote to be understood in the glimpses which we might imagine as filtering through. The vegetative level does its work with little ability to store memories that would be intelligently interpreted by the level of consciousness, because it is below the conscious experience of our actual lives. We sometimes have dreams that are indescribable and yet seem very real while occupying the field of partial consciousness. What these represent it is difficult to say. There may be more truth than is generally suspected in the humorists' view that such dreams are due to indigestion, and they may be awakened memories of the vegetative functions aroused, for instance, by combat with a Welsh rarebit or a broiled lobster. However, we can probably arouse no memories, at least of the lower levels, back of the beginning of our actual lives.

When the lower levels are awake and the higher levels are asleep the acquired experiences and associated memories of the latter are as if they had never been. A lay writer of fiction a number of years ago vividly portrayed this state of mind in the hero of "Looking Backward,"[2] when, after the readjustment of the world according to the author's plan, he dreamt he was back again in our civilization; and most of us can remember dreams in which we more or less realistically lived over some portion of our lives. "The mental processes in sleep are natural for that grade of consciousness or mental evolution. Thus we find that creative activity is slight or absent; there is regression to past (adult, childhood and infantile) experiences and tendencies; and the play on our emotions and instincts is marked and free."[1]

In other dreams the higher levels are awake and their memories are apt to be the ones retained. When the lower levels are asleep and the higher awake, some of the inhibition due to aroused memories of experiences stored in the lower levels—fears and limitations because of failures and disappointments—is more or less removed and daring mental flights are accomplished. The "astral body" of the Hindu, if it has any relation to reality, may exemplify this state of mind. "Where the appeal to our instincts is not especially direct, strong, selective, intimate, or individual significant," (*i. e.* when the lower levels are asleep and the instinctive tendencies dormant in consequence), "association and flight of ideas may be marked, rapid, superficial and quickly changing. Intellect, critique, correct interpretation, etc., are below normal. The mental mechanisms may run riot."[1] The instincts are probably to be here regarded as the revised experiences and memories which have accumulated from the beginning of animal life—the further back they were acquired the more ingrained and less understandable to the conscious areas, they are. Instincts of self preservation and race preservation are amongst the earliest; many shades of secondary instincts founded upon these have grown up till Man is—what he is.

Hoch[3] describes fever deliria with variations in the level of consciousness, but he regarded it from a different angle. While pointing out the difference between the temporary impairment of function in fever and the permanent loss due to actual destruction of nervous elements, as in the general paralytic, he does not think it necessary for his purpose to explain further why the level of consciousness should vary. He mentions it as a fact that proves there is no actual loss or destruction of nervous elements (in the fever deliria) to account for the clouding of consciousness, as almost full consciousness can be aroused by an effort. This seems very much like sleep, the higher and more vulnerable areas being, as in fatigue, more readily overcome, in this case by the toxic material of the infectious process—more readily narcotized—while the older, lower and consequently (we may assume) more stable, levels are incompletely or not at all rendered unconscious. Lacking the continuous, complete, normal, associative inhibitions they exhibit the fluctuations in the coherence of thought and the associated disorientation, etc., which we call delirium. The action of "general" anesthetics likewise points to a similar process, wherein the more highly differentiated areas are first overcome, while the lower functions are carried on with but little disturbance until the dose is overwhelming. In the later amentia, as for instance, after defervesence, where the level of consciousness does not vary and where so-called Freudian complexes are apt to be in evidence, the impairment is a more subacute process and may be definitely limited to the associated areas of one level, the disease having found one (more vulnerable) level which it temporarily puts out of business more completely.

A word might here be said of the appearance of wish-fulfilment in dreams, thus showing the analogy to the amentias in which wish-fulfilment is frequently present. There is probably no more common wish present in the lives of many of us

than that we might live our lives over again and order them differently. In the conception of what determines the content of dreams hinted at above, it is quite to be expected that the higher associated areas or levels of intelligence being asleep and their later acquired experiences and memories being out of the way as inhibiting factors, the earlier acquired memories should appear in the earlier and lower levels of conscious elaboration, occupy the field of partial consciousness, and thus allow us to live our lives over. People who have long since died come upon the stage: the memory of their death is asleep in the galleries: and we hear them talk and plan and we enter into their conversation and arrangements as we would have done when alive, but (while vaguely and intangibly, because unreal) perhaps with some added experience and judgment. The wish-fulfilment of the dream is apparently very real while it lasts, but there may not be so much symbolism about it as there is significance; and it may not be so much because it is a subconscious wish that it appears prominently in the lower level of consciousness as because we have given it rather more reflection than other thoughts. Other dreams and conditions which are regarded as wish-fulfilments might be similarly explained.

The sexual dream is usually frankly expressed.[8]

Such a dream as fleeing from danger in sand or other soft and impeding substance might lead one to think the motor areas were asleep while the areas concerned in storing the *memories* of motion, with possibly other associated areas, were awake.

The dream of stumbling, or falling, which is suddenly arrested, may be due to certain activities present in an awake area wherein the dream motion is produced, but the asleep areas are awakened through alarm reaching them by means of their associations. In some dreams one stumbles, or falls through space, and disaster is apparently averted by a general awakening of many associated areas. We may imagine imperious impulses reaching them from their neighbor of so urgent a nature as to have in effect the same result as the sudden violent knock upon the door of an actual sleeper, only to be informed on awakening that it was all a hoax, a false alarm, a sort of joke (if you will) that one area has played upon the others.

Reports of the post-mortem investigations which are being made of the brains of dementia praecox patients will be of great interest. Lambert[10] has stated that function is more subtle than structure and shows that clinically senile changes frequently antedate any microscopically discoverable changes in the brain. The same may be found true in dementia praecox. We already know that in some dementia praecox cases that have gone to autopsy changes have been found.[11] These will, in due time, be confirmed as more or less constant, discredited as unimportant and adventitious or set aside as undetermined in their relationship.

Some application of the idea of varying susceptibility of the different levels or areas of consciousness above referred to might be made to the psychoses in which definite tissue loss or impairment cannot be demonstrated. The higher emotions of patriotism, honor, shame, etc., are the latest acquired; and the most highly differentiated cells or areas, wherever they may be, are probably where they have their seat. These are the most vulnerable at least to senile changes and they lose their "function" (i. e., undergo invisible changes) before they display microscopically detectable deviation from the normal.[10] We observe that in dementia praecox a loss of affectivity is an early and progressive accompaniment and frequently persists during remissions otherwise quite promising.[11] The emotions being impaired, with possibly other correlated acquirements, by disease of the higher levels of consciousness, the dementia praecox may relive the complexities of his former life, while still retaining considerable contact with the outer world, and frequently, as in catatonia, actually seem to live a dream. It is conceivable that the gradual extension of the process to other areas is what causes the progressive dementia; and the brains of those who have shown unmistakable signs of dementia would be particularly interesting. That some, especially certain catatonics, recover, may indicate no more than that the underlying disease process is not always hopeless and incurable, and it is possible that the affected cells have undergone structural changes somewhat less than would be detectable at autopsy. Then, too, there is a probability that all parts of a normally associated area are not impaired together, resulting in variations. Similar inferences may be drawn in the psychoses which are known to be usually recoverable, and it may be that it is the less recently developed cells that are affected in these cases, being temporarily more susceptible for some reason to a different causative influence; but, on the other hand, more stable and less liable to permanent injury.

This takes no account of the *cause* of psychoses not demonstrably organic. It only hints at the possibilities which dream processes may exhibit in the way of explaining how some of the clinical manifestations of various psychoses are brought about, and to point out the fact that there may be a more definite relation than has been thought between the manner of production of the clinical manifestations of various psychoses, when the endocrine imbalance, or whatever it may be[12] that causes the psychoses considered functional, shall have been discovered.

The theory that different areas are differently responsive to a subtle organic cause yet to be discovered may not place the problem of the re-education of the insane in a less prominent position than it now occupies. If, during the actual life of the individual, so-called functional development (obscure and, as yet, unrecognizable structural change) thus takes place, there may be reason to believe that this constructive faculty is not necessarily lost in all cells because of the impairment of some areas, or associated areas. It may follow that re-education is the "functional" development of the unimpaired cells or areas along the same developmental lines; and the success of re-education, so far as the factors present in the patient are concerned, would depend to some extent on whether the assumed disorder or disease process causing the original impairment or loss (certainly loss of function) has been arrested or to what extent the re-education can outstrip the deteriorating process if still in progress, and it may show why deterioration ensues upon the discontinuance of the re-education.

If an underlying causative endocrine imbalance be discovered it may be that more healthy *ideation,* acting upon the vegetative nervous system through the representations of that system in the cortex, may, with or without other therapy, bring about an adjustment; and thus both psychoanalysis and re-education be entitled to all that has been claimed for them and more. So that, even if it be shown that the underlying cause of some mental conditions, regarded as psychogenic, though it be a subtle one, is essentially organic, these resources will still be available, though supplemented by chemical and other therapeutic measures.

Those who are brought daily into contact with the insane must frequently feel that real derangement of the "works"—the brain—exists in many forms of insanity in which no organic cause can be definitely ascertained. That any amount of bad habits of adjustment[4] long continued, or of turning away from reality[5] long persisted in, until it has reached the extreme divergence of the actual psychosis, can *alone* ever get a person into the state which presents, may some day be more than doubted. Many patients seem powerless to help themselves, although they have will power enough in other directions. Their antics, mental and physical, may be comparable to those of a chicken with its head cut off; and, figuratively speaking, a similar disaster has happened to many of them.

From what has been said I would conclude that:

1. Dreams occur when some areas of the cortex are awake while others sleep.

2. Some areas are more vulnerable than others, the susceptibility varying possibly (a) In sleep with hte kind of fatigue; (b) In psychoses with the nature of the toxins or deleterious agents.

3. Observation of dream phenomena may help to correlate the clinical manifestations of various psychoses.

4. Various psychoses exhibit parallel, but more extended, processes.

5. The ratio between functioning areas and non-functioning areas in dreams is inverted in the psychoses; hence, in the latter, contact with the environment is greater.

6. The discovery of an organic etiological factor in the psychogenic disorders, as in the organic group, will aid in a better understanding of the method of production of their clinical manifestations; and,

7. When discovered, psychogenesis may still be considered an important etiological factor.

8. The value of resorting to psychoanalytic, re-educative and other therapy may be enhanced by the discovery of underlying organic causes of insanity.

PRACTICAL METHODS OF HEART STUDY AND THEIR RELATIVE VALUES.

By W. D. ALSEVER, M.D.,
SYRACUSE, N. Y.

THE clinical study of diseased hearts has two objects—the establishment of diagnosis and the formulation of treatment.

Diagnosis to be complete must be tri-phasic—it must be etiologic, pathologic, and functional. The data necessary for diagnosis are assembled by three methods—history taking, physical examination, and laboratory examination. It is difficult to say that one of these three methods is more important than another; but it is true that often one is stressed and another minimized, thus distorting the picture produced in the clinician's mind.

History taking is slighted more often than either of the other methods. It is well known that doctors often obtain brief and inexact histories. In a recent discussion a busy practitioner said: "If you doctors had to see as many patients and travel as far in a day as I, you would not spend so much time in careful study of your cases." The answer came promptly—"If you would make a careful examination at your first visit, many of the subsequent visits would be unnecessary." Still more deplorable is the habit of many able men of assigning history taking to assistants, reserving the physical examination for themselves. I believe that only through a painstaking, personal discussion with the patient and his associates can the clinician obtain an exact and complete history. It requires the stimulus of responsibility in the case to lead any doctor to obtain "the truth, the whole truth, and nothing but the truth." One who takes histories *only* lacks initiative and his responsibility is nil. Being human he permits inaccuracies and omissions, and he fails to follow up leads which would stimulate his interest if he was to make the diagnosis. Only through careful history taking is the clinician likely to obtain the intimate knowledge of the patient's personality and habits necessary for full understanding of the situation. In no other way can he so easily establish the degree of confidence and respect necessary to insure the patient's full cooperation in the treatment. A detailed study of the patient's past goes far toward assuring the success of psychotherapy, an important element in the treatment of nearly all sickness. I believe that, in general, history taking calls for greater ability and considerably more time than physical examination.

In heart disease the history goes far in determining the cause of the defect and the functional capacity of the heart. Mere statements that the patient has had certain diseases, as syphilis, rheumatism, or hyperthyroidism, are not especially helpful, for inquiry regarding the course of the sickness will occasionally develop the story of some other venereal infection, myalgia, or simple goitre

instead of the diseases named. The symptoms and complications of previous diseases and the rate of convalescence from them should be known in order to estimate correctly their relation to the defective heart. Having elicited a history of acute arthritis, one should question carefully in the attempt to ascertain its primary focus, if such there be, otherwise the fundamental cause may never be discovered nor treated. Tonsils may have been inflamed many times without appearing to be grossly diseased; teeth with abscessed roots may look all right, but have a bad history; cholecystitis is notably elusive to physical examination, but may have caused suspicious sickness in the past. Inasmuch as degenerative heart lesions are the ones most often needing treatment, it is essential to inquire in great detail regarding habits of life, both recent and remote. Has the patient gone to excess in either work or play, or, quite as important, has he done too little of them. Has he eaten excessively or fast; has he specialized in meats or sweets. Has he slept too little. Has he carried unusually heavy mental burdens, either real responsibilities or foolish worries. Is there reason to believe he has had chronic errors in metabolism. Has his life been unbalanced in any sense. One must know how the patient has actually lived, not accepting the patient's opinion regarding excess, else the underlying cause of the degeneration may not be corrected, and downward progress will continue in spite of remedial treatment. Along with the loss of cardiac reserve power there usually comes a train of symptoms, some of which often are not elicited when the history is taken, and which may be misinterpreted if no physical signs of heart disease have developed. Weakness, dyspnea, pain and palpitation on exertion are the commonest symptoms, but not necessarily the first to attract the patient's attention. The weakness of cardiac failure is peculiar in that the patient is usually most conscious of it in his chest, while in other debilitated states, and also in health, fatigue from walking or running is usually most troublesome in the legs. Weakness which is most marked after a night's rest is not to be mistaken for cardiac weakness, although it may be a manifestation of some error in metabolism which can become a cause for cardiac deficiency. Sleeplessness, unusual nervousness and irritability are early symptoms. Indigestion, giddiness and faintness, and perhaps scanty urine and loss of weight are occasional early symptoms. Precordial tenderness is a sign of cardiac fatigue, but it may give an exaggerated impression because of an unusually responsive nervous system.

The history gives us better light on the functional capacity of the heart than any other source of information. Various tests based on pulse rate, blood pressure readings, and the intensity of heart sounds have been introduced for this purpose, but none of them has even reasonable accuracy. The best test is the one used by our fathers—have the patient exercise until short of breath; note the amount of work endured; observe the general condition of the patient as he rests, his apparent fatigue, color, severity and duration of dyspnea, behavior of pulse, occurrence of anginal pain, etc.; then judge roughly how the patient compares with the normal for his age and type. But all such tests are subject to modification because of the psychic state which is commonly associated with a complete examination. A careful inquiry into what has happened in the past, day after day, will let us know if the patient's endurance is defective and will give us a good idea of the degree, duration and course of the weakness. Unfortunately there is as yet no accurate arithmetical measure for cardiac strength. But if a man can do an ordinary day's work with only ordinary fatigue, his cardiac reserve is good regardless of what physical examination may show.

The importance of estimating functional capacity has not been appreciated fully. Our attention has been focused rather on structural changes, yet we know that it matters little what congenital or acquired defects exist in a heart if only it works well. We often find organic changes of long standing in senile people. The practical question is not how is the heart built, but what can it do. The discovery of a valve lesion or other defect should not condemn a patient to a cardiac cripple's life. We admit with shame that our profession has brought up many children to lives of semi-invalidism because they had functional murmurs or sinus arhythmia, and that many adults have led sheltered lives because of an incorrect diagnosis of organic disease with no attempt to estimate cardiac efficiency. Particularly in degenerative lesions reserve power is impaired long before abnormal physical signs are evident. If diagnosis waits on physical signs then treatment does not begin until defects are well established. If diagnosis is made when reserve power begins to fail, treatment is begun when the trouble is most easily curable, treatment is simpler and shorter and prognosis far better. It seems as if beginning degeneration cried out to us for recognition. Early cases will rarely be recognized except through study of the functional capacity, and defects in functional capacity can be detected most surely and early through careful history taking.

Really all that has been said about functional capacity applies to the whole circulatory apparatus, not only to the heart but also to the arteries, kidneys and blood. The signs of circulatory weakness may be due equally well to disease of any of these tissues. Deficient capillary flow is really what we are diagnosing; that is what causes dyspnea, anginal pain and quick fatigue. Heart disease is rarely limited to the heart and eventually the entire circulatory apparatus is impaired. Having diagnosed circulatory weakness it is desirable to ascertain the location of the pathological changes. But when the etiological and functional phases of the diagnosis have been established, treatment should be begun at once without waiting for structural changes. If the etiology is given due consideration, one can hardly go wrong in the treatment, and cure or a stationary stage may be arrived at without the development of gross physical signs of disease.

Physical examination leads to the recognition of abnormal physical signs. They are usually incontrovertible evidence of structural change. Disease necessarily existed before they became evident, so they may be looked on as comparatively late

signs of heart disease. Failure to recognize disease before the development of physical signs does not mean that disease was absent, but it does demonstrate our incompetency.

We all were taught to proceed methodically with inspection, palpation, percussion and auscultation, but the fascination of murmurs leads the average doctor to reverse the order and probably omit inspection and palpation entirely. Perhaps we all are occasionally guilty of this fault. The most important single observation in the physical examination of the heart is the determination of the location and character of the apex beat. This can be done best by inspection and palpation. If the patient leans slightly forward as he sits or stands, examination of the apex beat will be easier. If he is in the recumbent posture throughout, no examination of the heart can be satisfactory. If he lies on his left side the apex beat will be displaced to the left. If the impulse is so feeble that inspection and palpation do not detect it, auscultation may be used to locate the point of maximum intensity of the sounds, which will often, but not always, be the position of the apex beat. If the apex beat is normal in location and force, there can be no gross defect in cardiac efficiency, hence the importance of this part of the examination.

A vibratory sensation felt by the palpating hand should not be counted as a pathological thrill, unless it can be recognized with ease.

Estimation of the actual size of the heart through percussion of relative cardiac dullness is the source of many disagreements among doctors. The best method in my opinion is light percussion, carried on parallel to the ribs and beginning at least two or three inches beyond the expected limit of cardiac dullness. This is to be done when the patient is sitting or standing and leaning slightly forward. In case of doubt I am accustomed to use immediate percussion, that is, to tap with the percussing finger directly on the chest wall; and again to check this method by auscultatory percussion, that is, by listening with the bell of a stethoscope an inch or two above the center of the line along which I propose to percuss and noting the sudden change in conduction of sound as the percussing finger enters or leaves the area of cardiac dullness. Fluoroscopy will check these methods, but it is not infallible. If during fluroscopy an opaque pointer is pressed against the chest wall at the margin of the cardiac shadow, it will indicate, with reasonable accuracy, the limit of the heart at that level and can be compared with the limit obtained by percussion. With care all the above methods usually can be made to agree and, I believe, will give a correct impression of the heart outline, particularly the lateral limits. Ordinary *x*-ray plates are notoriously inaccurate for this purpose, because of the diverging pencil of rays. If the tube is fixed at 6 feet from the plate, a nearly correct picture is obtained, but this method, I believe, has no important advantage over those already described. The orthodiagraph gives probably the most accurate picture of the heart's size, but it requires special skill for operation and is rarely available. Estimation of the outline of the heart to determine whether it is of the aortic type or mitral type, is best done by the fluoroscope or *x*-ray picture.

Percussion has been in use since the time of Hippocrates, but auscultation was discovered by Laennec in 1816. Some one said that before Laennec's discovery: "Clinical observation, though never blind, has been always deaf." So much harm, as well as good, has been done by auscultation that Sir James Mackenzie has questioned if the world would not have been better off if the stethoscope had never been invented. Be that as it may, there is one region of the heart which has long been known as the region of auscultatory romance and the experiences of the late war have led us to disregard systolic murmurs, unless accompanied by ample proof of their significance. Mackenzie has well advised the profession that, if careful examination elicits only one sign of heart disease, the heart should be considered normal. Beyond all doubt, this applies to murmurs. In order to interpret murmurs properly hearts should be auscultated in both the upright and recumbent positions and before and after exercise. Even then much difficulty will be experienced in diagnosing the significance of murmurs, and the causes of many of them will remain undetermined. The diastolic blow of aortic regurgitation, the presystolic or diastolic roll of mitral stenosis, and the friction sound of pericarditis are the only abnormal heart sounds of great diagnostic significance.

That inexhaustible subject for discussion at afternoon teas—blood pressure—is of only little use in the diagnosis of diseases of the heart itself. In aortic regurgitation there is a large pulse pressure corresponding to the Corrigan pulse. Auricular fibrillation can be diagnosed by listening to the absolutely erratic variations in force of beats and intervals between beats as the column of mercury falls. These variations are more evident near the upper limit of systolic pressure. Pulsus alternans can be diagnosed by noting the sudden doubling of the pulse rate as the column of mercury falls; the new beats being weaker and being inserted midway between the original beats. Other irregularities cannot be diagnosed by the sphygmomanometer.

The polygraph and electrocardiograph are necessary for the careful study of irregularities, but they are not always available nor are they essential for diagnosis except in certain cases. Sinus arrhythmia should be recognized because of its absolute harmlessness. Nearly all of the irregularities of youth are of this type. Practically it is safe to say that any irregularity which continually repeats itself in each respiratory cycle is sinus arhythmia. In case of doubt an instrumental investigation must be made. All of the other irregularities are due to myocardial defects. Premature beats are found in a majority of people after midlife; consequently their harm must be insignificant. On palpation or auscultation one may recognize with ease that an occasional beat is weak and occurs prematurely. There may be confusion between premature beats and partial heart block, in which case instrumental examination is necessary. A regular pulse of 30 to 40 per minute, not transient, is almost surely complete heart block. All forms of heart block should be recognized because they are dangerous.

Pulsus alternans and paroxysmal tachycardia should also be diagnosed because of their seriousness, the former by the sphygmomanometer as al-

ready described, and the latter by noting the absolutely abrupt onset and offset of a regular series of fast beats. Auricular fibrillation and auricular flutter are important because of their response to digitalis. Auricular fibrillation may be detected while taking blood pressure. Any pulse rate over 180 per minute is undoubtedly flutter. I have no desire to minimize the importance of the polygraph and electrocardiograph, but they are not always available and, inasmuch as a correct diagnosis can usually be made without them, it is particularly important that these simple methods be familiar to everyone.

Laboratory diagnosis is of great importance in the study of heart disease, but only in the etiologic aspects. It is of quite as much negative as positive value. Syphilis of the heart is only rarely to be diagnosed without a positive Wassermann test. A clean-cut history of the usual course of the disease with the certain knowledge of improvement under treatment might sometimes be accepted as proof. A positive culture for diphtheria will explain the cause of some cases of heart failure during convalescence from sore throat. A positive blood culture is presumptive evidence that a recent heart failure or inflammation is due to the germ recovered; if multiple emboli occur the diagnosis is beyond question. In the absence of a positive blood culture, the detection of bacteria in localized foci of inflammation is less valuable presumptive evidence of the same diagnosis. For example, gonococci in the genital tract and streptococci in the tonsils. The complement fixation test for gonorrhea, if positive, is proof of the activity of the gonococcus in the body and would suggest a probable relation between the gonococcus and any existing inflammation of the heart. A negative test is of little value. Blood counts diagnosticate severe anemias and leukemias which may not only cause the symptoms of circulatory weakness, but also murmurs and enlargement of the heart. The quantity and character of the urine and the quantity of nitrogen waste in the blood help to differentiate nephritis.

It is my desire to call attention particularly to the methods for the early diagnosis of heart disease and to urge their importance. Americans have been given to excesses of all kinds, and consequently show much circulatory wear after forty. If doctors would recognize cardiac weakness by symptoms rather than wait for physical signs, ten to twenty years would be added to the lives of our efficient, but misguidedly strenuous men. In America we have a particularly large field for the study and treatment of potential heart failure. It is one of the great needs of our country.

There is much about heart disease to remind one of tuberculosis. It must be recognized early in order to be treated while still in a curable stage. Symptoms, with or without physical signs, are of great importance in diagnosis and are important beyond measure in early treatment. Faulty habits of living are fundamental in either condition; exhaustion and errors in metabolism preparing the soil for actual disease. Careful and long continued regulation of the mental, motor and digestive functions is essential to the best results. The end result will often be a cardiac or pulmonary cripple, without active disease, able to do a limited amount of work, and reasonably sure to live many years in comfort if he daily conforms to his new rules of life. Both are without specific treatment, but depend rather on rest for the diseased organ and general supportive treatment. Our attitude toward these two conditions should be more nearly the same than it has been in the past. Tuberculosis formerly meant death, it was recognized late, and treatment was ineffectual. Now we have advanced so that our attack is mainly on the prevention and early treatment of the disease. Prevention, rather than cure, is the watchword. May that also be our goal in heart disease.

DUODENAL ULCER.

ITS EARLY DIAGNOSIS AND TREATMENT.

By NATHAN H. HORNSTINE, M.D.,

PHILADELPHIA, PA.

Dr. Bertram W. Sippy of Chicago and Dr. John B. Deaver of Philadelphia, both eminent authorities, in discussing recently the treatment of Duodenal Ulcers before the Philadelphia County Medical Society, agreed that the only treatment for a duodenal ulcer is its excision, a gastroenterostomy performed and the patient is discharged as cured.

An excellent modus operandi, indeed, and no one will deny the fact of its advisability, but, as Dr. Deaver so aptly stated, and Dr. Sippy agreed with him, 100 per cent. of all the cases of duodenal ulcers are brought to the operating room after they are at least of nine years standing, by which he meant to imply that it takes at least nine years for an ulcer to develop and become mature before any surgeon may operate.

Quite a happy state of affairs, indeed! If we are to take this for granted, it means that the general practitioner treats his patient for nine years for some gastric trouble or other and eventually prepares for the surgeon a beautiful case of a gastric or duodenal ulcer.

As broad as the assertions of Drs. Sippy and Deaver may be, yet most general practitioners will have to admit its truth, and why? This is just the aim of my paper.

The general practitioner, however, must not alone be blamed for letting the ulcer mature and eventually land on Dr. Deaver's operating table. The patients themselves, in 75 per cent of all the cases, are the contributory cause of the same. The patients do not seek the doctor's advice right after they get their first symptoms in the gastric region; instead they resort at first to home remedies or advertised nostrums and when they do come to the physician, before the latter has a chance to study the case, the patient not getting immediate relief begins to travel from one doctor to another and each one diagnoses and treats his case, but not for the right ailment.

It requires, on the part of the general practitioner, the use of a little diplomacy to handle the cases that come to him for treatment. He must, at all times, suggest to his patient that, though he may not be able to give him immediate relief, he will, however, in the course of two of three weeks after

careful study of his case, arrive at a definite diagnosis and save him from the necessity of a subsequent operation and probable death.

The physician, must in all instances, when a patient with whatever gastric troubles comes to him, have on his mind the ultimate result of an ulcer, whether duodenal or gastric.

It may be somewhat too broad or too sweeping a statement to make that every case that presents itself for treatment of gastric troubles must be looked upon as a subsequent case of an ulcer. I will, however, say that in 90 per cent. of all the cases the process of an ulcer does begin as a mere irritation and break in continuity of the mucous membrane of the stomach, and then, depending upon the degree of the patient's vitality and the degree of the activity of the entire alimentary tract, the further development of such process may either lead to the formation of an ulcer proper or it may abort itself by a spontaneous proliferation of epithelial tissues and thus close itself up and become "cured."

It may be also stated, with a certain degree of positiveness, that when a commencing ulcer does not abort itself and is allowed to become "matured" and reaches the operating table, the patient, on leaving the hospital pronounced "cured," is by no means cured; he is relieved for a while, for perhaps a year or two, but he usually comes back to the general practitioner for some ailment or other in his abdominal cavity, whether adhesions due to the operation, a probable developing gastric carcinoma, or just a simple gastric neurosis. The patient, long after an operation has imaginary pains which are due to the psychic effect, produced by waiting nine years, living through all the sufferings of agony and pain, and only at the end to be operated upon.

Indeed, what a happy state of affairs it would be if we would only realize that an early diagnosis of a duodenal ulcer would mean the saving of thousands of lives and reduce the suffering of gastric pain to a minimum. The proverb that a "stitch in time saves nine" would be realized here. By the "stitch," however, I don't mean a surgical, I mean a prophylactic, which is the ounce of prevention.

The excision of the ulcer, even in the hands of the skillful surgeon, is, at times, a very serious procedure. It is possible with a great degree of safety, when on the anterior wall, but even then is accompanied with danger of pyloric stenosis; while the resection of the duodenum proper is not advocated by many surgeons because of its great mortality.

Every surgeon will admit, when doing a gastroenterostomy and closing up the pylorus, that no matter how skillful he may be, it is as hard to keep a natural opening closed as it is to keep an artificial opening from closing. The peristaltic action of the stomach will for a long time carry the digested food toward the pylorus and there, not finding its usual outlet, the food will remain for a while, causing a hypersecretion of HCl, and perhaps in time, due to the constant irritation, this will cause a new ulcer to develop; at any rate will give great discomfort and pain to the individual. Though this may happen seldom, yet it does happen in a certain percentage of cases. Dr. Deaver himself mentions one case in a fine, benevolent gentleman, a clergyman, upon whom he operated for ulcers at least four or five times, and who eventually died. Dr. Deaver called this the case of a man predisposed to duodenal ulcers. Another fact which must be borne in mind in some cases, where an artificial passage by gastroenterostomy has been made, is that the food coming into the stomach rolls quickly to the artificial opening, falls "pell mell" into the jejunum and results in a peptic ulcer in the jejunum. Fluoroscopic examinations have proven this to be true in the case of patients upon whom a gastroenterostomy has been done, for when barium or bismuth was given, it could be seen that the powder sifted right through the opening.

The man with the "new opening" in the stomach feels always hungry; he never gets enough. The surgeon ascribes this to the enormous appetite the patient acquires after the operation. To the internist, however, to whom this patient comes a while after the operation, this does not seem to be the fact. The internist finds that this man, though devouring a great quantity of food, yet receives very little nourishment. He is emaciated, pale, anemic, and loses weight.

Now, what are we as internists to do—not to sow the seeds for the surgeon to reap the harvest? How are we to prevent the duodenal ulcer from becoming "matured"? The answer is obvious. Do not let your patient wait and linger and then begin your active treatment when it is too late, when surgical intervention is the only remedy to prevent perforation, hemorrhage, or pyloric obstruction, etc.

If your patient is placed on a diet after the operation, why not place him on the same diet long before the operation—just as soon as you make your early diagnosis of an ulcer in its first stages of development. Yes, this is just the point. How can we arrive at an early diagnosis?

In the 16 years of my practice I have been fortunate enough to observe more than 100 cases, with only one case that was operated upon for a peptic ulcer on the posterior wall at the greater curvature of the stomach. Though every case that presented itself for diagnosis had different aspects from the point of view of general symptomatology, yet most of them, 95 per cent., presented similar gastric symptoms. I have observed that the male is more commonly affected than the female. As to age, there is no limit, at least from 20 to 70. The patients were apparently well until the first attack of a burning sensation in the stomach or a feeling of pressure in the epigastric region. The feeling of pressure which is at times experienced with a sensation of pain that usually appears in the afternoon, or in the first half of the night, also a few hours after the main, heavy meal, should lead us to suspect a duodenal ulcer.

From the anamnesis or the study of the previous histories of the cases under observation, I have found that in the uncomplicated cases the patient awakens in the morning absolutely free from any distress or feeling of pain and remains in this state until the food of his first meal reaches the duodenum, and the heavier the meal, the later his troubles begin. This seems to prove that the so-called "hungerpain" is not a positive factor in the diagnosis of duodenal ulcers, because when the

stomach is at rest from midnight until morning, the patient is free from pain.

Another significant symptom, though not observed in every case, and which is present in most of the cases, is the "water brash" which is the erructation of an ill-smelling fluid containing no particles of food and which is different from the regular vomitus containing particles of digested and undigested food occurring often in pyloric obstruction. Though the symptom of water brash may somewhat mislead us, as it may be due to a cardiospasm or a retroperistalsis, yet it is invariably present in duodenal ulcers, and in conjunction with the other symptoms will lead to a positive diagnosis.

All these, of course, are subjective symptoms and are elicited from the history of the patient. Now, how are we to make our diagnosis? On what subjective symptoms must we rely with surety to arrive at an early diagnosis of duodenal ulcer?

Inspection aids very little in the diagnosis. A gastroptosis or a carcinoma may be diagnosed by this sign. Direct palpation and percussion of the epigastrium are the most significant aids in the diagnosis of duodenal ulcer. Directly to the right of the linea alba, about midway between the border of the lower ribs and the umbilicus, there can invariably be found a round or oval area of pain on the slightest pressure, which varies with the size of the ulcer present, and which diminishes in size with time as the healing process goes on. In neurotic patients who suffer from hyperesthesia, a sign similar to this may be found, but it will cover a larger area. It is advisable, while percussing or palpating over this area, not to use strong force, just a very light, gentle pressure or light tapping with the finger, or better still a small, light percussing hammer may be used. In order to ascertain with more positiveness the existence of this sign, the procedure may be repeated every day for a few days, and if the sign still persists you may with assuredness say that you have diagnosed a duodenal ulcer.

Of course, the laboratory findings of the stomach contents, the blood in the vomitus, the occult blood, the percentage of HCl are of the greatest diagnostic value, and must be applied in every case. Roëntgenology, though a great aid in the diagnosis, is at times very uncertain, and as regards the early diagnosis at least of an ulcer absolutely unsafe.

Having thus arrived at an early diagnosis of duodenal ulcer, long before symptoms such as perforation, hemorrhage, or pyloric obstruction appear, we can with certainty commence our medical treatment, and prevent these latter symptoms, save our patient from the operating table or perhaps from the undertaker's table. I say an early diagnosis, because when a patient comes with a chronic condition, with a nine-year-old ulcer, then the surgeon as our "ultima ratio."

Before we commence our medical treatment, we must strongly impress on our patients that at any time they begin to feel a little better, they are not as yet altogether cured. They must for a long period of time continue with their treatment, with their mode and habits of living, and particularly with their specially prescribed diet.

When we first see our patient and find on palpation and percussion over the "pain zone," in the right epigastrium to the right of the linea alba and midway between the lower border of the ribs and the umbilicus, that significant symptom of pain to be present, we order our patient to bed and cover the area with moist heat. This may be best accomplished by a folded towel wrung out of hot water, over which is placed a hot water bottle, the patient lying on the right side so that the hot water bottle may rest on the bed at his side and not cause heavy pressure on the stomach. The next most important thing is the diet. For the first three days milk should constitute the chief diet, with one or two very soft boiled eggs (boiled one minute.) After the third day, in addition to the milk, a cup of chicken broth and soft boiled eggs may be given. This is to be continued until the end of the first week. After the seventh day, in addition to the above, provided the pain in the percussion zone has modified, a small amount of strained potato soup with butter, but without salt, may be given. At the end of the second week, when all the symptoms have abated, small portions of zwieback or crackers may be allowed and a little farina added to the milk. After three weeks, if the patient shows good progress, the menu may be increased to milk, soft boiled eggs, toasted bread with butter, broth, and one or two broiled lamb chops. The quantity and quality of the above diet may be increased gradually in accordance with the progress the patient is making.

In any instance, it is imperative for the physician to regulate the diet in accordance with the progress of the condition, and not allow the patient himself to deviate or change the diet. The physician must always be on the alert in watching the progress of his case and not arrive at conclusions too soon, believing that his patient is already cured. It may take weeks and sometimes months before a cure can be effected, depending on the degree of severity of the case in hand. Rest in bed must be of four to six weeks' duration in every case.

Medication plays another important role in the treatment of duodenal ulcers. Something must be given to counteract the hyperacidity of the stomach which, so far as is known, is the chief etiological factor causing gastric or duodenal ulcers. Before we commence, however, with our therapeutic agents, we must bear in mind that as the duodenum is the receptacle of the bile and pancreatic juices, we must see if the liver and pancreas, producing these juices, are in good working order. Autotoxemia from the large intestine, due to retention of fecal matter, produced often by constipation, may cause untoward effects on the small intestines, the duodenum and stomach included. Putrefactive gases in the stomach and intestines must be gotten rid of. In a word, we must always be on the lookout for that "vicious circle," the duodenum, and the stomach being the center of all the troubles in any diseased condition of the human body. No matter what part of the human economy is affected, the stomach acts as the receptacle of various drugs and articles of foods and is being naturally affected by it.

Bismuth is being used extensively, but it has a tendency to produce constipation, being often prescribed in cases of diarrhea. Atropine and belladonna are drugs given with a view to check the secretion of HCl, but these drugs check also other

secretions and cause a dryness of the throat. Silver nitrate is a good drug, but can not be used for a long time as it causes argyria. The following is a prescription which I have used with good results:

℞ Sodii sulphatis 30.0
Sodii phosphatis 30.0
Sodii bicarbonatis 40.0

M. Sig.: One teaspoonful in a wineglass of hot water three times a day before each meal.

This combination has a tendency to overcome the hyperacidity of the stomach and the patient taking it is free from the feeling of distress he had before. A smaller dose of the above may also be taken after meals by those who begin to feel this distress coming on an hour or two after meals.

We are well aware that the nervous system, the branches of the sympathetic coming from the celiac plexus entering into the many ramifications with the vagus, plays a great part as the controlling power of all the secretions and may be considered as one of the leading etiologic factors in ulcers of the stomach and duodenum. This branch of the nervous system must be considered in the treatment of ulcers. The phosphates seem to exert a sedative effect upon it, and sodium phosphate, used in the above prescription, is the most acceptable form in which it may be given in conditions of gastric or duodenal ulcers.

As I have already stated, obstipation must in all instances be overcome in the treatment of duodenal or gastric ulcers, and I believe the sodii sulphas (Glauber's salt) also one of the ingredients of the above combination is a happy remedy for the same. The sodium bicarbonate needs no introduction, being an antacid which is a good neutralizing agent in every case where hyperacidity must be overcome.

In conclusion I will say that an early diagnosis of duodenal ulcers is absolutely possible and must be made; and in most cases medical and dietetic treatment, when early instituted, will surely overcome the condition.

All chronic cases that come with a history of passing from one doctor to another for several years, or cases of perforation, hemorrhage, or pyloric obstruction, must and should be referred to our surgical friends.

530 Spruce Street.

BIDDY AND THE COAL BIN.

A CASE OF POLYGLANDULAR DISEASE.

By ROBERT L. PITFIELD, M.D.,

PHILADELPHIA, PA.

Biddy G's life had been since childhood a drab one; much pain and suffering had been added to a colorless existence. Nothing had sweetened her life, her home was humble, she had but few, if any, friends other than her family; she never had married, and probably never had a beau; she had a loyal and devoted sister who mothered and nursed and supported her for years. The devotion of this sister was touchingly heroic; her life, too, was drab because of Biddy's complaints.

When I first saw the patient she was a gaunt, grotesque woman of 42. Her face was striking in that it was devoid of any pleasing or intelligent expression, her countenance was as wooden and expressionless as an Alaskan totem pole. Dark violet shadows encircled her eyes, her eyelids were slightly puffy and hung above her lustreless eyes, whey-colored bags faintly greenish in cold lights. Fixed wrinkles encircled the corners of her rigid lipped, austere mouth; the lines never came from smiling but from grim mental pain. When she spoke, the stiff parchment-like skin of her face seemed to smother any expression that would have liked to have appeared from beneath.

Her dull reddish hair was dry, coarse, and unshining. Her neck was long and haggard, the skin hung in thin folds; there was no hint of any thyroid swelling such as should be seen in the throats of most healthy women of her age. The outer halves of her eyebrows were slightly thinned. As she sat in her chair her attitude was ungainly and wooden. She replied when addressed, but never ventured a remark. Her speech was slow, with a suggestion of scanning in its cadence. Even if her health had been good, her intellect never could have been vigorous. Instead of being plump and rosy, as are many Irish women of her age, she was as sapless and seedless as a bit of dried apple.

Her sister, a poor hairdresser, brought her to me because she said that Biddy was a great care to her, was melancholy, had "heart spasms," and could not be left alone. When it was necessary for the sister to go out and earn a few dollars and Biddy was left to herself, she could always be found upon her sister's return sitting in the gloom of the coal bin in the cellar twisting a certain lock of her hair; a bald spot was shown to me where the hair had been pulled out. Biddy's thoughts were more in harmony with the gloom of the coal bin than with the sunlight; a mind in woe cannot endure the sight of happiness in others, and the coal bin shut out such painful spectacles. She loathed people, too, because her queer appearance attracted inquisitive looks, but she went to church whenever she was able. About her neck were hung at least six religious emblems suspended by as many cords and ribbons, and above her heart was pinned another; her morbidness, as is usual in such cases, colored her religion, and she had many fears. Her past history was poor in the following particulars: in her childhood she suffered from a severe attack of scarlet fever, later she had a bad fall down the cellar stairs, and in her thirties the menopause was abrutly precipitated by an oöphorectomy. Since her operation her health had steadily declined; she never had been able to work, did not read, conversed but little except to her sister and then in a peevish vein always. She could knit a little for a few minutes at times, but her span of attention was very short. If she walked much she was at once seized with heart spasms, and these heart attacks terrified her and her sister dreadfully. Her heart was not manifestly enlarged, but its impulse was weak and the pulse was rapid. A faint nitral murmur, systolic in time, was heard. Her blood pressure was low, vasomotor relaxation was manifested by puffiness about the ankles, but true edema pitting on pressure at times was found along the shin bone. Her reflexes were prompt and otherwise normal; a history of syphilis was not elicited; her pupils were equal, responding to light.

It was manifest that this asthenic waif was profoundly neuropathic from some somatic causes, and that these causes were of endocrine origin was most patent. Her thyroid was an impalpable remnant of a normal organ. As has been noted she had no ovaries. There is no doubt that other of her ductless glands were hypoplastic and defective in function. I made no tests of the glucose tolerance of her pituitary gland. Her precordial pains were more than neurasthenic; there was evidently some myocardial weakness. According to Hirshfelder, when there is some minor cardiac defect in the presence of hyperexcitability of the nervous system, anginal symptoms are apt to appear. Hirshfelder classes such a syndrome as one of the five forms of angina pectoris. Her kidneys were normal, she was markedly anemic, and was habitually costive. With no palpable thyroid, dry skin, brittle, scant hair, and a marked neuropathy, the indications for thyroid administration were marked. Immediately after the exhibition of a few grains of the medicament the patient became more cheerful and inclined to like the sunshine; she shortly forsook the coal bin and would sit for hours on the doorstep and watch children play at jackstones and marbles. After a time her sister found that she could leave her for all day; she smiled and looked more cheerful, and was happy in a new vigor that she had not known since her youth, but there was always a pronounced fatiguability, and she was always neuropathic. The temptation of all doctors is to administer too much of a medicine that is acting well, as thyroid did in this case; I gave her too much; her need was comparatively little. She became dyspneic, her heart enlarged, more edema appeared in her feet. The amount, I think, was but 6 grains per diem, but this was sufficient to increase the rapidity of the pulse, and also increased the precordial pain. It became necessary to stop the drug for a few weeks, and digitalis was given in the interim. One grain of thyroid extract t.i.d. was enough to make her comfortable; in some mild cases 1/20th grain or even less is sufficient.

For observation purposes a stay in a hospital was suggested, and to this proposal she gladly acquiesced, much to my surprise. In the ward she made some friends, was happy and contented. In the effort to supply any further glandular delinquencies corpus lutein was administered, but without benefit. For the cardiopathy 1-grain doses of pituitary extract were given. This was followed by great improvement, both physical and mental, and she took this drug for two years with a like amount of thyroid extract. She became less of a burden than before to her sister, and more of a companion, and would help in the small affairs of the tiny home.

The relative economic value of a few hundred tablets of thyroid in that home was enormous. The hairdresser could attend to all of her customers, prosperity began to bless them, they abandoned the single room in the lodging house, and acquired a small house, and Biddy did most of the housekeeping.

Thyroid cannot cure such cases, it can only supply the deficiencies of a crippled gland. After the menopause patients previously thyroprivic can sometimes abandon the drug, as without the menstrual function less demand is made upon the thyroid than before; in this case, however, there was no such event to look forward to.

Thyroid, as I have previously pointed out, is the nutritional hormone of the body; in some cases of hypothyrosis with a psychopathy the results from its administration are magical. In Biddy's case it lessened the invalidism to a degree that made life bearable and sunny to both sisters. An influenzal pneumonia closed the life of this poor creature.

Comment.—The polyglandular chain in this case had suffered two traumatisms; scarlet fever affected some of the components in the chain, a devastating operation had further disturbed the balance of a weakened system interdependent upon its various parts. Thyroid extract weakened the heart, as it is most prone to do in certain cases. Pituitary acted as an adjuvant most happily in restoring muscle tone to the heart, and in other metabolic ways, probably. It is always well to begin with too small a dose than too big a one, especially in the presence of a weakened heart.

5211 WAYNE AVENUE.

ERRORS IN THE DIAGNOSIS OF THE CONTAGIOUS DISEASES.

BY ARTHUR I. BLAU, M.D.,

NEW YORK.

DIAGNOSTICIAN, DEPARTMENT OF HEALTH.

SERIOUS consequences may result, both to the individual and the community at large, from faulty diagnosis of the contagious diseases. Unfortunately, such diagnostic errors are by no means rare. The fact that these errors can be avoided in the great majority of the cases, by the observation of but ordinary precaution and a little painstaking, renders the matter the more regrettable.

A careful investigation of the cases in which erroneous diagnoses were made, has revealed the following factors as being responsible for such occurrences, given in their order of importance and frequency: (1) Carlessness in arriving at a diagnosis. (2) Not holding a case under observation when in doubt. (3) Not utilizing laboratory tests at one's disposal. (4) Deficient knowledge and experience in the contagious diseases, both theoretical and practical. (5) Anxiety of the patient's kin for an immediate diagnosis.

Carelessness in Arriving at a Diagnosis.—I find that this factor is responsible for most instances of faulty diagnosis. The carelessness is displayed in the inquiry, in the examination, in the differential diagnosis, or in the deductions. Any one of these is incompatible with a proper diagnosis. If the doctor ignores or dwells but superficially upon the information that he may receive from questioning the mother or other kin of the patient, he loses a valuable asset in the diagnosis. Knowing how long the patient has been ill, the manner of onset, the course of the disease, and, if a rash was or be present, how long its duration and where noticed first, which he can know by merely asking, his understanding of the case will be materially enhanced.

The previous history of the case, which is often neglected, is equally important; in fact with the contagious diseases, it is very important and sig-

nificant. And again by merely questioning the mother, the doctor can know, almost definitely by wisely putting his questions, whether the child has had any of the contagious diseases, a knowledge which might be of considerable assistance in ruling out those diseases.

Last, but not least, interrogation will reveal a possible exposure to any of the contagious diseases, a point of some bearing in the etiological consideration of the disease in question. I find that pitfalls in the diagnosis are often due to the lack of appreciation of these points in the history. Not infrequently the history of the case is entirely ignored, the doctor launching at once into the examination of the patient.

The examination in itself is often conducted but superficially. The doctor is apparently satisfied by merely baring the child's chest slightly, giving the rash present a casual observation, and with an air of bravado and self-importance, makes a snap diagnosis. Examination of the throat is often omitted. If that organ is examined the pathological conditions therein are either overlooked or defectively valued. The thermometer is made use of but infrequently. If it were used, fever might be discovered, which would indicate, or rather ought to indicate, that that sign, together with a sore throat or a rash, or all the three combined, is very suspicious of some contagious disease.

While faulty history-taking and careless examination account for most erroneous diagnoses, the stumbling block in many cases seems to be the differential diagnosis. Even assuming that the doctor has a fair knowledge of the contagious diseases, he fails to appreciate the significance of the leading points in the case; he either under or overvalues these points. He mistakes one rash for another, regards the eruption as due to indigestion or some dietetic indiscretion, takes tonsillitis for diphtheria, or vice versa, takes cervical adenitis for mumps or mumps for adenitis, or takes pertussis for bronchitis or nasopharyngitis or vice versa, and so on *ad infinitum*.

By failing to grasp the true significance from the history and examination the doctor, naturally, makes false deductions. It is just like an example in arithmetic, errors in the addition or other problem lead to a faulty answer. The same thing applies with like veracity in the contagious diseases, errors in the examination or other diagnostic step, lead to a faulty diagnosis.

Not Holding a Case Under Observation When in Doubt.—As a cause of erroneous diagnosis this factor ranks next to carelessness. In any diseases, but in the contagious diseases in particular, a correct diagnosis is often impossible on the first examination of the patient. No matter how expert a man may be in the subject, he will often be unable to decide offhand what the rash is, or what the sore throat is due to. If the first examination is made during the initial stage of the disease, correct interpretation is doubly difficult. Hence the value and frequently necessity of observation, a fact not thought of by many practitioners. Particularly in dealing with the contagious diseases is it imperative to be absolutely sure of the diagnosis, for a wrong diagnosis reacts unfavorably not only upon the patient but also upon the community at large. Through failure of keeping a doubtful case under observation many localized epidemics of the contagious diseases have occurred.

Not Utilizing Laboratory Tests at Disposal.—This applies exclusively to the diagnosis of diphtheria. This disease is often overlooked by the neglect of the doctor to take cultures in cases of sore throat. I find that follicular tonsillitis is very often mistaken for diphtheria, or vice versa. The mucous deposit on the tonsils in cases of scarlet fever is often ascribed to diphtheria. All these errors could be avoided by the taking of cultures. Very often a sore throat, with no evidence of any exudate, diphtheritic or otherwise, is due to diphtheria, which can only be shown by cultures. Nasal diphtheria, similarly, is often overlooked. Apparently cultures do not enter the mind of the doctor when he has a case with a persistent nasal discharge.

Deficient Knowledge and Experience in the Contagious Diseases.—Although as a cause of erroneous diagnosis this factor, fortunately, is only of minor importance, yet its occurrence now and then makes it a point to be considered. This factor is especially applicable to the younger and less active practitioner. Many doctors see contagious diseases but rarely, and even their theoretical knowledge on the subject has withered. Therefore it is not surprising to find these men guilty of making false diagnoses. They are lost in the diversity of the contagious eruptions.

Anxiety of the Patient's Kin for an Immediate Diagnosis.—In a small percentage of cases, pressure on the physician by the patient's kin for a quick opinion on the nature of the illness, is responsible to some degree for the erroneous diagnosis. The mother is anxious to know what ails her child, and the doctor to satisfy that anxiety is apt to make a premature diagnosis. In many instances he cannot express doubt or uncertainty, because that would reflect unfavorably upon his professional prestige. This state of affairs is particularly emphasized in a practice among the poor and the unintelligent.

To illustrate the common errors made in the diagnosis of the contagious diseases, the following cases will be cited. These represent but a small percentage of the cases incorrectly diagnosed by different practitioners. All the cases occurred in the first four months of 1920.

CASE I.—J. P., 8 yrs. Scarlet fever taken as a gastrointestinal rash. A doctor saw the case twice, at an interval of ten days. In consequence of the wrong diagnosis the child was allowed to go to school. The school nurse in her routine examination of school children, noticed desquamation on fingers of patient and promptly sent the child home. I saw the case soon after and on examination found a marked generalized desquamation. The child had been ill 17 days before the condition was finally recognized, by mere accident. Apparently the attending doctor overlooked the case, and even attached no significance to the desquamation, which must have been apparent on his second visit. Due to the mistaken diagnosis, this child had mingled freely with his friends and was daily attending school, subjecting all those with whom he came in contact to the danger of contracting the disease.

CASE II.—A. J., 14 yrs. Urticaria taken as scarlet fever. Child excluded from school and otherwise quarantined. Diagnosis rectified after two days and child released from quarantine. Such cases give rise to great and unnecessary annoyance.

CASE III.—M. S., 4 yrs. Disagreement between two doctors, one making it scarlet and the other a mere "cold." Examination showed definite desquamation of the fingers and toes, which should have been noticed by the doctor diagnosing the case as a mere cold. Case scarlet fever.

CASE IV.—A. M., 3 yrs. Disagreement between two doctors, one saying it is scarlet and the other diphtheria. Neither correct. Examination showed no evidence of either disease. Culture was negative, but was not taken by either of the medical men. Case acute nasopharyngitis.

CASE V.—R. W., 4 yrs. Scarlet fever taken as simple sore throat. Doctor saw case on the first day of illness, rash developed on the following day. If the doctor were not so sure of his diagnosis and kept case under observation for a day, he probably would have made correct diagnosis. Case scarlet fever.

CASE VI.—O. W., 17 yrs. Measles taken as scarlet fever. This mistake is frequently made. Close observation of the rash in this case would have revealed a few maculopapules, which taken with a careful history would have avoided erroneous diagnosis.

CASE VII.—W. B., 7 yrs. German measles mistaken for scarlet fever. This error is rare.

CASE VIII.—S. G., 4 yrs. Scarlet fever taken as German measles. Such errors are common. The diagnosis of German measles should not have been made until scarlet fever could be ruled out definitely. German measles is relatively infrequent, except in epidemics, and most nearly resembles measles. Mild forms of scarlet are often taken for German measles.

CASE IX.—M. V., 8 yrs. Follicular tonsillitis taken as diphtheria.

CASE X.—R. K., 6 yrs. Diphtheria taken as follicular tonsillitis. Cases Nos. IX and X represent the most common diagnostic errors. If cultures were taken such errors could be avoided. Diagnostic errors in throat conditions may lead to serious consequences. The danger of taking diphtheria as tonsillitis is, of course, the more damaging.

CASE XI.—J. M., 18 mos. Diphtheritic croup taken as simple croup. This was treated for two days, without the true nature of the disease being recognized. When I saw the patient he was moribund; his life was prolonged a few hours by immediate intubation. This error is not infrequent, and in seriousness has no equal.

CASE XII.—R. J., 23 yrs. Chicken pox taken as small pox. If the doctor had observed eruption closely, he would have seen the characteristic crops of varicella, a picture quite different from the shotty papules of small pox.

Innumerable other diagnostic errors are daily made, which could be avoided in most cases. It is the duty of the physician, therefore, in justice to himself, the patient, and the community, to use all his energies and all the means at his disposal to make a correct diagnosis. This can be done without any great travail. A detailed and careful history should be obtained, both present and past, dwelling particularly on the contagious diseases. Information should be sought on a possible exposure to contagion.

The examination should be conducted carefully, having the patient stripped, and particular attention being given to the condition of the skin and the throat. The rash, if present, should be thoughtfully scrutinized. Having completed the examination, the points of difference of the contagious and other possible diseases should be considered, and deductions therefrom carefully made. The doctor should not allow himself to be influenced by the desire of the mother for an immediate diagnosis, unless he is sure of his ground. Cultures should be taken in doubtful sore throats without delay. In fact it is a wise policy to take cultures in all cases of sore throat in children.

If in spite of all these manoeuvres, no definite diagnosis can be arrived at, the patient should be held under observation until the development of additional signs and symptoms.

It stands to reason that no intelligent examination and interpretation is possible without a fair knowledge of the subject. It behooves the doctor, therefore, to acquire that knowledge from a practical and theoretical study of the subject. That is absolutely essential, for without that he is "like a house without a foundation."

417 EAST EIGHTY-THIRD STREET.

THE TREATMENT OF CANCER.

BY ROBERT BELL, M.D., F.R.F.P.S., ETC.,
LONDON, ENGLAND.
PHYSICIAN IN CHARGE OF CANCER RESEARCH, BATTERSEA HOSPITAL.

TWO interesting, but by no means conclusive articles, which appeared in the MEDICAL RECORD of March 8 (page 415) and of March 20 (page 503), prompt me to offer some remarks bearing upon the views expressed by Dr. Wm. Mayo of Rochester, Minn., on the one hand, and on the other hand by Dr. S. M. D. Clark of New Orleans, and Dr. James F. Percy of Galesburg, Ill., upon the treatment of cancer.

Now I don't wish to be hypercritical, but from 26 years' close study of the cancer "problem," or rather "enigma," as I have put it in an article in the MEDICAL RECORD of Feb. 20 last, I have been compelled to place surgical treatment, *ultra vires*, when cancer is concerned. Surgery has had too long an inning, without, as far as I can ascertain, and most markedly in my own experience of 15 years' treatment by the knife, obtaining a successful result. From my standpoint, therefore, I have been forced to the conclusion that the time has arrived when the physician should be called in, and show what he can do, as regards both preventive and curative measures. To quote one of Dr. Mayo's sentences: "We must spread more widely the *fact*"—italics are mine—"that chronic irritation was the cause of the disease." No doubt it may be the exciting cause of the disease by providing a nidus upon which to locate itself, yet this will only obtain when a toxic condition of the blood is in evidence, which latter is the predisposing cause of the malady. And I am convinced it is only by adopting, and continuing, those measures which will promote the continuance of a healthy blood stream, that we can ensure immunity from this scourge. There must be no means neglected—the aim of which should be to make autotoxemia an impossiblity, for in that lies the *fons et origo mali*.

In this connection I may state that a daily, complete—and I use this word advisedly—evacuation of the bowels should be insisted upon. The home should be thoroughly ventilated, more especially the bedrooms, the windows of which should always be kept sufficiently open to permit a free access of fresh air—for breathing a vitiated atmosphere is quite as much a toxic agent as absorption of noxious fluids from the unduly retained excreta in the colon. Then our dietary should not be so much restricted to devitalized material as the conventional custom of today indicates. Our blood requires for the satisfactory nourishment of our cells, the *living*

principle of plants and fruit, just as that of every other animal does. This unfortunately has had conferred upon it the erroneous term of "vitamines," which is a contradiction in terms; as whoever heard of a living amine—an ammoniacal substance? As the first who called attention to the necessity of these substances as being essential to a healthy blood condition, I have named "vitols." They, together with the contained organic vegetable salts, which are also deteriorated by cooking or frequently lost altogether, when the water in which vegetables are boiled is thrown down the sink, are essential to health.

Then we should bear in mind that the eating of butchers' meat is only taking food at second hand—moreover, we know it is the product of the lowest stratum of vegetable matter. We must also bear in mind that the decomposition of the effete matter derived from this, when it is received into the colon, gives rise to the most noxious form of toxins. It is also advisable to drink more water than is usually the custom, so as to flush the kidneys.

In the many hundreds of cases of cancer that I have met with, I am unable to remember one instance where constipation was not coincident; also, as coincident, a tendency to rheumatism; and, as a rule, flesh meat eating was prominently in evidence.

In the MEDICAL RECORD of June 5, 1915, a paper of mine appeared upon "The Natural History of Cancer," in which I think I proved that cancer is in reality a form of fungoid growth, and that, like vegetable fungi, it can grow only upon a soil pregnant with decomposing matter; and can thrive only upon a vitiated blood stream, which represents the soil in this instance.

My contention is that in the surgeon's mind concentration is too earnestly fixed upon the local outcrop—for the local manifestation is only an outcrop—of the disease, which, long before this has manifested itself, has been latent in the blood. Hence the fact that rheumatism is generally found to have been in existence prior to the cancer incidence, and it will be found that microphotographs of cancer blood, and those of the blood taken from rheumatic subjects, bear such a strong resemblance to each other that it is impossible to decide which is which. Therefore, if the prevention of cancer is to be assured, the integrity of the blood must of necessity be maintained. Moreover, if it is to be cured, and this has frequently been effected, we must adopt measures to cleanse the blood from the pernicious contents which have been responsible for the malign metamorphosis that has taken place in cells, which, otherwise, would never have been guilty of exchanging normal physiological control and consequently healthy metabolism, for that which develops cannibal instincts.

If ever cancer is to become a disease of the past, it must be looked upon and treated as a blood disease, primarily and essentially. But simultaneously hot air—I employ it up to a heat of 170° Fahr.—may be driven locally, under a pressure of at least three atmospheres, right into the heart of the tumor; by which means the death of the cancer cells will be accomplished long before those of the normal tissues have been endangered.

In the May 1st number of the MEDICAL RECORD appears an article upon "Magnesium in Cancer," which I welcome most heartily as, for some months past, I have found great benefit derived from the subcutaneous injections of 2 cc. Oscol Mg. (colloid magnesium) three times a week, but, of course, in conjunction with dietetic and hygienic treatment.

15 HALF MOON STREET, W.

X-RAY TREATMENT OF UNIVERSAL PSORIASIS.

BY JOHN REMER, M.D.,

ROENTGENOLOGIST VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY

AND

W. D. WITHERBEE, M.D.,

ROENTGENOLOGIST ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

NEW YORK.

THE various methods used in the treatment of psoriasis previous to the advent of *x*-ray therapy are no doubt familiar to all. The treatment of a case of universal psoriasis with chrysarobin, salicylic acid, white precipitate, etc., was rather a complicated and disagreeable procedure for the patient as compared with present-day methods of *x*-ray therapy.

The *x*-ray exposures are preferably given three times a week, allowing a day between each exposure. For the first treatment the head and arms are exposed; the second, the trunk and buttocks; the third, the legs and thighs.

The head is divided into five areas, as in the Adamson-Kienbach method for ringworm of the scalp; the arms, forearms, and hands into four areas each, two flexor and two extensor; the trunk into eight areas, four ventral and four dorsal; the buttocks, one area for each buttock; the leg and thigh into six areas, three anterior and three posterior.

The dose given these cases is one-eighth of a skin unit to each area of the scalp each week until four treatments are given. Then scalp treatment is discontinued for four weeks, and if necessary a second series of four treatments is given. Then scalp treatment is discontinued for four weeks, when, if necessary, a third series of four treatments is given. To each of the areas of the body one-fourth skin unit is given each week until the lesions have disappeared. The treatment is concluded in from four to eight weeks, depending on the severity of the case.

If it is impossible to follow the above method, which we consider the ideal one, then the body is divided into two divisions, and each is treated once a week, using one-eighth of a skin unit for each area instead of one-fourth on body areas.

The dose of unfiltered ray in these cases may be obtained from any set of factors by the use of the formula published in the June, 1917, issue of the *American Journal of Roentgenology*,[1] or in a more recent article in the May, 1920, issue of the *Archives of Dermatology and Syphilology*.[2]

For example, take the factors given in a recent article on Plantar Warts: 7½ in. gap, 4 M.U., 9 in. distance—determine the time necessary to produce one-fourth of a skin unit.

$$\frac{7\frac{1}{2} \times 4 \times ?}{9 \times 9} = \frac{30}{81} = \frac{10}{27}$$

9/16, the standard for 1 skin unit divided by 10/27

$$= \frac{9}{16} \times \frac{27}{10} = \frac{243}{160} = 1 \text{ min. } 31\tfrac{1}{8} \text{ sec.} = 1 \text{ skin unit;}$$

¼ of 1 min. 31⅛ sec. = 23 sec. = ¼ skin unit;

$$\therefore \frac{7\tfrac{1}{2} \times 4 \times 23/60}{9 \times 9} = \tfrac{1}{4} \text{ of a skin unit;}$$

⅛th of a skin unit = ½ of 23 sec. = 11½ sec.;

$$\therefore \frac{7\tfrac{1}{2} \times 4 \times 11/60}{9 \times 9} = \tfrac{1}{8}\text{th of a skin unit.}$$

The factors above were used in the treatment of plantar warts,[2] and with 1 1/6 minutes time the dose is said to be 1 1/3 skin units. This we are unable to verify. Thus:

$$\frac{7\tfrac{1}{2} \times 4 \times 1\ 1/6}{9 \times 9} = \frac{35}{81} \text{ divided by 9/16 of the standard for 1 skin unit} = \frac{35}{81} = \frac{16}{9} = \frac{560}{729} = \frac{3}{4}+ \text{ skin}$$

units instead of 1 1/3 skin units.

The time necessary to produce 1 1/3 skin units with these factors would be:

$$\frac{7\tfrac{1}{2} \times 4 \times ?}{9 \times 9} = \frac{10}{27};$$

$$\frac{9}{16} \times \frac{27}{10} = \frac{243}{160} = 1 \text{ min. } 31 \text{ sec.} = 1 \text{ skin unit;}$$

1/3 of 1 min. 31 sec. = 30 1/3 sec.

30 1/3 sec. + 1 min. 31 sec. = 2 min. 1 sec. = 1 1/3 skin units.

It is evident from the foregoing that ¾+ skin units was given instead of 1 1/3 skin units, as indicated in the paper.

During the past year approximately 100 cases of universal psoriasis has been treated successfully by this method. While relapses do occur, they are in no way more frequent nor of greater severity than in other methods of treatment.

Mammary Hypertrophy Cured by Injection of Milk.—Patel reports this example of autotherapy. Patient was a woman of twenty-four, nullipara, who had developed mammary hypertrophy as a sequel of influenza. The condition was becoming aggravated and Bier's cups could withdraw no milk nor otherwise benefit the condition. Months elapsed, during which the condition became progressively worse, the hypertrophy being great, with much pain and tension and a general inflammatory appearance. Mouriquand then suggested the injection of human milk, 5 cm. every second day. At the end of a fortnight the amelioration was considerable. Eventually the cure was complete and even during the menses there was no reaction. A biopsy showed that the hypertrophic mass consisted of mammary elements, fat and young connective tissue cells. The entire process was deemed of infectious origin. Mouriquand stated in discussion that he had only sought to test the reaction of the breast to milk, and that the sudden atrophy had come as a surprise.—*La Presse Médicale.*

Medicolegal Notes.

Expert Opinion as to Effect of Narcotic on Credibility of Witness Held Inadmissible.—Testimony was introduced tending to show that a witness in a criminal prosecution was addicted to the use of morphine and other narcotics. It was held that the trial court did not err in refusing to permit expert testimony to establish the fact that the use of such drugs tends to render a person unreliable in his statements and generally untruthful. The court quoted State v. King, 88 Minn. 172, 92 N. W. 965, where a like question was involved, to the effect that the witness was before the court and jury. His appearance, demeanor, and the manner in which he gave his testimony, whether straightforward and unequivocal, or in a manner indicating untruthfulness or an unbalanced mind, were sufficient from which his credibility could be determined. —Katleman v. State, Nebraska Supreme Court, 175 N. E. 671.

Failure to Diagnose Correctly Not Necessarily Malpractice.—In an action for the removal of plaintiff's appendix contrary to her wish that it should not be done if she were pregnant, it appeared that the operation disclosed that the plaintiff was about 2½ months pregnant, and that she had an inflamed appendix covered with a Jackson's membrane. The appendix was removed and she made a normal recovery, and in time gave birth to a living and healthy child. The medical testimony showed without dispute that the failure to accurately diagnose her condition was due neither to lack of care, skill, nor judgment; that under the conditions as they appeared an early operation was advisable; that the operation was skillfully performed; that she made a normal recovery, and was relieved from a menace that might have resulted very seriously during later pregnancy by having to have the inflamed appendix removed. In view of such testimony it was held that the trial court properly directed a verdict for the defendant. When a physician exercises that degree of care, diligence, judgment and skill which physicians in good standing of the same school of medicine usually exercise in the same or similar localities under like or similar circumstances, having due regard to the advanced state of medical or surgical science at the time, he has discharged his legal duty to his patient. Where due care, diligence, judgment and skill are exercised, a mere failure to diagnose correctly does not render a physician liable. Not omniscience, but due care, diligence, judgment and skill are required of physicians. When they meet such test they are not liable for results or errors in judgment.—Jaeger v. Stratton, Wisconsin Supreme Court, 176 N. W. 61.

Whether Fall or Disease Proximate Cause of Death.—In an action on a policy insuring against death from accidental injury, "independently of all other causes," there was evidence that the insured had cirrhosis of the liver, and that seventeen days before his death he had suffered a fall on a staircase, which was claimed to have caused his death. There was a conflict in the expert testimony over the theory of one of the plaintiff's medical witnesses that death resulted from a traumatic thrombus, or blood clot, in the portal vein, caused by the fall, "starting thrombosis" of that organ, of which defendant's three medical witnesses denied the possibility, and the length of time before the cirrhosis and admittedly infected condition of the bile ducts and gallbladder, which the insured's physician stated the insured had for years, would necessarily terminate fatally. It was held, by a divided court, that the question whether the insured's death was caused by an accidental injury, independent of all other causes, was for the jury.—Abbott v. Travelers' Ins. Co., Michigan Supreme Court, 176 N. W 473.

State Statute Making Medical Examiner's Report Conclusive Only Applies After Policy Is Issued.—The Iowa Supreme Court holds that Iowa Code, Section 1812, making the medical examiner's report conclusive on the insurer, unless procured by fraud, does not limit, prior to the issuance of a policy, the insurer's investigation as to the applicant's assurability to the examination of its local medical examiner, but applies only after a policy has been issued.—Reynolds v. Northwestern Mut. Life Ins. Co. (Iowa), 176 N. W. 207.

PAPILLOMATA OF THE LARYNX IN CHILDREN.

IN general practice one not infrequently sees cases of hoarseness in children the cause of which is not easy to determine. Very often there is no history of "a cold" either in the head or chest. Sometimes the hoarseness is continuous. If one could inspect the larynx one would see in many of these cases, numerous cauliflower-like growths attached to the arytenoids and false cords, and sometimes filling up the larynx to a degree that interferes with free respiration. These little tumors are multiple benign papillomata, and are found in most instances before the age of fourteen—in other words they precede puberty, and if let alone tend to atrophy and disappear when the period of adolescence is well under way. They are important in general practice because they are not suspected as a cause of the hoarseness. A diagnosis of diseased tonsils and adenoids is made and the little patient is submitted to an operation which does nothing to relieve the condition. Since it is so very difficult to examine the larynx of a child by the laryngoscopic mirror, the diagnosis must be made by direct view, that is with the instruments of Killian, Brünings, or Jackson.

Papillomata of the larynx occur about equally in the two sexes. Many are undoubtedly congenital, but no one seems to have been able to establish any hereditary tendency to their formation. Syphilis has been accused as an underlying condition, yet the growths are found in many non-syphilitic children. Tuberculosis also has been suspected, but the microscope shows nothing in the removed masses to confirm this suspicion, and the various tests—von Pirquet and others—are commonly negative. Some observers have thought the neoplasms to be consequent upon various exanthemata, but there is no proof of this. One curious feature is that these growths never become malignant in children, but in adults they may become carcinomatous—in fact, they so much resemble cancer that the pathologist must be on his guard when sending in a report on the tissue section.

In 1881 Chiari removed the masses under direct vision in two cases without anesthesia. This was thought at the time to be an exhibition of great skill, as cocaine was not then in use and the peroral tubes carrying electric light were unknown. The laryngologists of that day favored thyrotomy, but the tumors recurred so promptly that it was very discouraging. Clubbe reports a case in which he did thyrotomy 17 times. The result was a fistula of the larynx, stenosis, and loss of voice. This procedure has been almost abandoned by the surgeon of to-day. Several writers (Mackenzie, Hodkinson, Massei, and others) have reported favorably on tracheotomy, leaving the growths to take care of themselves. It is said that upon giving the larynx a rest, the growths gradually disappear. After O'Dwyer had given his method of intubation to the world, various surgeons thought that by inducing continuous pressure upon the papillomata, the tendency to recurrence would no longer obtain. But prolonged wearing of the tube produced necrosis, spurs of new tissue, and vocal weakness. Arsenic and potassium iodide have been administered with the idea of "building up the system" and thus reducing the growths. It is doubtful whether this is ever possible. Some writers have praised the galvanocautery, thinking that, if the base of the growth is burned, recurrence is minimized. Various acids, such as lactic, monochloracetic and trichloracetic, and chromic, have been used. Likewise alcohol and formalin have both had their day.

Of late radium and the *x*-ray have had a host of supporters, especially in the United States. Robert Abbe and Harmon Smith have advocated the former, applying about ten milligrams in a specially constructed container for several hours. It is yet too soon to say whether this should be recommended as routine treatment. There is still difficulty about the dosage, and radium burns on mucous surfaces are by no means uncommon, and they may lead to ulceration, necrosis and ultimately to stricture formation. Fulguration after the well-known method of De Keating Hart is recommended by several French authors. But unless special apparatus is developed for this purpose it can have limited value. The long spark is absolutely essential, as De Keating Hart pointed out in his original monograph; the short spark causes burns, necrosis, and sloughing. It should not be necessary to say that fulguration should never be performed under ether anesthesia because of the certainty of fire; but we have heard of two fatalities because the operator evidently forgot this important fact.

At this stage of our knowledge and experience, it is probably better to remove as much of the papillomatous mass as one can by direct peroral laryngoscopy and then cauterize the base of the growth with the actual or electrocautery. Anesthesia is quite unnecessary in young children, as the operation takes only a very few minutes at each sitting and the amount of pain engendered is negligible.

DE SENECTUTE.

MANKIND'S three greatest evils are said to be disease, old age, and death. Disease is certainly an evil which can, however, in very great degree, be

prevented by rational hygiene and sanitation. Senescence may be no evil at all; it was not so to Galton, who wrote, at eighty-six, "I find old age to be a very happy time on the condition of submitting frankly to its many limitations." And one may very well doubt death to be an evil who has read of the nonogenarian aunt of Brillat-Savarin, for whom he cherished a very warm and mutual affection. When, on a visit to her he found her abed and very feeble, he tenderly raised her head and induced her to take some of his "most excellent and restorative wine," whereupon she thanked him and, sinking back contentedly on her pillow, said: "My dear, should you come to my years you will understand that the aged need death just as the young need sleep."

Some observations may be offered to the end that the era of the lean and slippered pantaloon may be comfortably lived. The aged digest more slowly than the young. Their bodies, indeed do everything more slowly. They should therefore not eat more than three times a day and if they hunger for it, something light at bedtime. Cheyne wrote early in the Eighteenth Century: "Every wise man after fifty ought to begin to lessen at least the quantity of his aliment; and, if he would continue free of great and dangerous distempers and preserve his senses and faculties clear to the last he ought every seven years to go on abating gradually and sensibly, and to the last descend out of life as he ascended into it, even into the child's diet. If men have been moderate smokers they should not have to give up a moderate indulgence in this habit in old age. Exercise should be moderate but gentle. Walks should be taken on the level or up easily graded slopes. Games should be such, croquet or golf and the like, as keep both the mind and the body pleasantly but not violently occupied. Thus may be avoided, or at least mitigated the autotoxemias to which those of advanced years are prone. And the venerable should rest often—taking naps whenever and as often as the disposition to sleep asserts itself. There must ever be warmth; for the elderly life is largely a question of that; the extremities especially should be kept warm and dry.

Those of the aged who are of independent means are fortunate indeed; money sufficient for their essential needs and comforts is in many cases better than medicine. Those who are wise then will prepare in middle life for some kind of annuity. And it is most advisable that old people should have hobbies, which they should have begun to cultivate in their prime. Nothing so sets into the grave the feet of an elderly man who has relinquished his life's vocation, as to be lacking in some avocation. There are many and most congenial hobbies to ride: Gladstone, for instance, was a Homer scholar; also a special student of the Scriptures in which capacity he occasionally had a "run in" with Huxley, and with results not always happy for himself. Disraeli wrote novels, which were above the average. Salisbury was an adept in electricity. Joseph Chamberlain was a cultivator of orchids. Billroth was a delightful pianist. In Boston, they have, or had up to a few years ago, a club of physicians who went in for chorus singing. Of all hobbies the most satisfying surely is the cultivation of music, "one of humankind's most inestimable blessings"; with perhaps, though not necessarily so, some little skill on a musical instrument.

The human mind and body should endure to the century mark rather than only to three score and ten. Especially should the mind remain sound by reason of our peculiarly generous cerebral blood supply. Haller, computing that human maturity is attained by the twentieth year, declared that the natural span of the genus *Homo*, after the manner of most other creation, should extend to five times twenty years. Buffon also held that the human span should be about the hundredth year. Metchnikoff was convinced, and in his book *The Prolongation of Life* went far toward convincing others, that it is very possible for human life to be lengthened a decade or two, at least, though he himself barely exceeded the Psalmist's three score and ten.

CHILD HEALTH CENTERS.

More than a quarter of a century ago Herbert Spencer asked: "Seriously, is it not an astonishing fact, that though on the treatment of offspring depend their lives or deaths, and their moral welfare or ruin, yet not one word of instruction on the treatment of offspring is ever given to those who will hereafter be parents? Is it not monstrous that the fate of a new generation should be left to the chances of unreasoning custom, impulse, fancy—joined with the suggestions of ignorant nurses and the prejudiced counsel of grandmothers?" To-day we are told that the average young mother has had no opportunity to learn how to care for her baby in a correct manner. The little knowledge possessed by her has been "handed down by word of mouth and retold with variations" and "is filled with superstitions and, at its best, is woefully inadequate." If the great philosopher were alive today he would doubtless be grieved to see that his plea for preparation, through proper education, for the important business of parenthood, has met with so little response; he would take some compensatory satisfaction, however, in the thought that at last well-directed effort is being made in many quarters to offset this lack of opportunity on the part of young mothers to acquire such important and far-reaching knowledge.

The Missouri State Board of Health, through its Division of Child Hygiene, calls attention in the *Public Health Reports* for July 30 (issued by the United States Public Health Service) to the fact that one of the most efficient plans for reducing infant mortality and promoting the health of babies and children of pre-school age is the establishment of baby health centers where the young mothers of the community may learn to care for their babies, and thus help to prevent the unnecessary deaths of 250,000 infant citizens of the United States every year. To this end the Division of Child Hygiene has issued instructions for the establishment and conduct of such centers, and has appealed

to local boards of health and organizations interested in community and health improvement to cooperate with each other and with State boards of health in promoting child health work. Such cooperation generally practised and wisely directed would certainly go far toward a material lessening of infant mortality and an elevation of health standards for children throughout the country. Incidently, the average of adult physical, mental, and moral fitness would undergo a commensurate evolution.

THE THERAPEUTIC VALUE OF RADIUM.

AT the recent meeting of the British Medical Association at Cambridge in the combined sections of gynecology and electrotherapeutics, Dr. Robert Knox of London presented a paper on the treatment of uterine fibroids by radiotherapy. In his opinion the following were the contraindications to treatment by *x*-rays or radium: (1) Calcareous degeneration; (2) Other forms of degeneration, if at all advanced; (3) Coexisting malignant disease unless considered inoperable; (4) Infection of the uterus; (5) Pelvic inflammation; (6) Inflammation of organs in the vicinity, *e.g.* cystitis, appendicitis, etc.; (7) Submucous pedunculated fibroids. It was pointed out that there were several disadvantages in this line of treatment, such as the long time taken to effect a result, treatment being given at intervals of several months. Moreover, treatment was not always successful; the tumor was often reduced in size, but did not disappear. The dangers which existed, such as burns, etc., were easily avoided if the treatment were carried out by an expert. There were, however, great advantages. The treatment was quite painless, there was no interference with the patient's routine of life, no operative shock, and rapid return to health when the hemorrhage had been arrested.

At the annual meeting of the American Radium Society, held in New Orleans in the early summer of this year, a paper was read on radium in toxic goiter, by W. H. B. Aikins of Toronto. The author said that he had had an experience of this form of treatment of goiter of about 100 cases and was fully convinced of its value. He pointed out that in applying radium over the thyroid gland, the effect required was one of deep penetration with a minimum skin reaction. In order to attain this result the radium must be so screened as to prevent the action of the short but powerful beta rays, and to obtain the benefit of the more penetrating gamma rays. Aikins laid especial stress on the remarkable results frequently obtained by treating the toxic goiter of adolescence by radium, and quoted Dawson Turner as to the superiority of radium over *x*-rays in the treatment of this disease when occurring in youth. He held that as compared with *x*-rays in the treatment of this condition, radium had the following advantages: (*a*) Absolutely constant emission of rays, and therefore exact dosage possible; (*b*) Far greater penetration so that the deeper parts of the gland are reached; (*c*) No noisy, exciting apparatus, so that the treatment can be applied at the bedside without in any way disturbing the patient. The words, "cito, tuto et jucunde," could fairly be applied, he said, to the radium treatment of exophthalmic goiter.

The views of the medical profession as to the therapeutic value of radium are becoming steadily more optimistic. In certain cases it can be employed by itself with most satisfactory results, that is, when the cases selected are suitable and the dosage efficient. In a large number of cases it is a valuable adjunct to operation. Radium would seem to be peculiarly well adapted for the treatment of toxic goiter, when combined with rest in bed, dietetic treatment, and drug treatment.

TREATMENT OF WHOOPING COUGH WITH ETHER INJECTIONS.

INTRAMUSCULAR injections of ether in pertussis were first recommended by Audrain in 1919 and Weill and Dufourt endorsed the resource as a marked addition to our armamentarium. Deherridon contributes an article on the subject in the *Journal des sciences médicales de Lille* for May 30, 1920, xxxviii, 22, in which he reports 30 cases of the disease treated by Dufourt's technique. This consists in the administration of one c.c. in 24 hours in children under 1 year and 2 c.c. in the same period for older children, injected three days in succession followed by a day's omission and then one final injection. Injections are made in the buttocks and have never done any harm and they are not painful if made deeply. A study of the 30 cases shows 5 failures. The number of paroxysms after each injection is used as a measure of the benefit, while the duration of the disease at the time of the treatment is an important factor. Thus in one case a boy aged 5 years had had the whoop for 15 days at the rate of about 13 paroxysms in 24 hours. He received 6 injections of 2 c.c. each and in 8 days was free from all paroxysms. A child aged 3 years who had whooped for 9 days at a rate of 10 paroxysms a day received 4 injections of 2 c.c. each. In 6 days the paroxysms ceased, but there was a relapse 7 days later of a milder type which yielded in 4 days to 3 injections. In one child who failed to benefit, the number of paroxysms remained constant at about 20 in 24 hours. In one patient who had developed bronchopneumonia the ether was well borne and served incidentally as a cardiac stimulant. The paroxysms of cough which had reached 35 in 24 hours improved notably under the treatment, and after the third injection were reduced in frequency to 15.

ROLE OF VITAMINES IN NUTRITION.

LUMIÈRE who has done considerable original work in this field sums up the subject briefly in *La Presse Médicale* for May 8, 1920, xxviii, 29. Eykmann initiated the study by the production of artificial beriberi in fowls nearly thirty years ago. Funk was the first to isolate a substance from the cuticle of rice grains which he designated as a vitamine. Since then an entire series of substances has been imagined which are as essential to nutrition as calories of fuel food, inorganic salts, protein, etc.

The exact nature of the vitamines remains undetected. It has been claimed that they are akin to the diastases but the author shows numerous important differences. They cannot act directly upon the food substances like enzymes—that is they cannot break up the molecules of the food and render them more absorbable and we have to ask if they could be of service in synthesis of these products of enzyme action into assimilable substances. In experiments on animals with decorticated grains the author found that loss of appetite is essential for the production of emaciation. Moreover there is a stagnation of the ingesta in the upper part of the digestive tube. Experiment appears to show that artificial vitamines overcome this stasis and that the stasis causes the anorexia and not the opposite, as might be assumed. The stasis appears in turn to be the result of lack of secretion and the latter is associated naturally with absence of appetite. In experiment, loss of weight often precedes loss of appetite, which shows that loss of secretion of the gastric and other juices manifests itself very quickly on the assimilation of food. The author has further learned that the cerebellar troubles which cause incoordination in a pigeon fed on decorticated rice are the result of cerebellar anemia, for inhalation of amyl nitrite temporarily restores the coordination. The author's results do not simplify the subject of vitamines, but rather tend to show the increasing complexity of the entire problem, for it is hardly likely that the main function of these substances is merely secretory.

Etiopathogenesis of Endocrine Syndromes.

Pentagna considers this subject in *La Pediatria* for May 15, xxviii, 10. His summary is as follows: An examination of 115 cases of endocrine dysfunction treated in the out-patient department of the Children's Clinic in the University of Naples since 1914, the patients coming from within the 20 mile radius, showed that in 46 per cent. there was a positive Wassermann which was supported by other evidence of syphilis. In nearly 30 per cent. syphilis was probable although not demonstrable, while in 23.4 per cent. the disease could be regarded as absent. The causal factors in these latter cases were narrowed down to alcoholism in the parents, endocrinic inheritance, and accidents in utero or during labor. Hence lues seems to be the most potent factor in endocrine pathology because of the action of its toxins during the developmental period upon the endocrine organs. The endocrine disorders present in the 115 chlidren comprised the following: myxidiocy, 52; Mongolian idiocy, 41; pluriglandular syndromes, 13; myxedema, 8; hyperadrenalism, 1. This classification seems strange to the American viewpoint. But myxidiocy is simply cretinism, or myxedema plus idiocy, and if to the 52 cases we add the 8 of simple myxedema we have the total of 60 cases of hypothyroidism. Mongolian idiocy is much more difficult to reconcile with the endocrine affections and the author does not seek to associate it with anomalies of any one gland or set of glands. Some cases showed hypothyroidism while in numerous others there was syphilis in the parents. Other conditions in evidence were rickets, muscular hypotonia, various developmental defects, etc.

The Toxic Coefficient of Alcoholic Beverages.

Duchesĉhi discusses in the *Annali d'Igiene* for February, 1920, xxx, 2, the action of ethyl alcohol with especial reference to various blood constituents, including cholesterine. In men who abuse spirits there is hypercholesterinemia which is seen in neither the abstainer nor the moderate drinker. Other results published appear to concern the experimental dog and need not be cited here. The author adds to his paper interesting data about the toxic coefficient of alcoholic beverages as obtained in Argentine, but these figures are calculated only for guinea pigs, and hence are of little significance in the case of man. The figures are for kilograms of animal weight. Concentration appears to be a factor, as the coefficient for rum of 70 proof is double that of 48 proof. The latter is much less toxic than 100 proof whiskey, being as 40 to 10. Brandy and gin of the same proof are less toxic than whiskey. The latter in fact has the same toxicity as absolute alcohol. Ordinary red and white wine have a low toxicity—60 to 85—while that of ale and beer is 150 to 200. There is a proportion between proof and toxic coefficient, but it is subject to much variation. The highest proof rum (110) is more toxic than absolute alcohol, while as already stated rum of 48 proof has remarkably low toxicity. Kümmel has a low toxicity, while anise spirit of the same proof has a high one. These differences in toxicity can be explained only by the presence of some other deleterious substance than alcohol.

Gas Gangrene in Civil Practice.

Duret considers this subject in the *Journal des sciences médicales de Lille,* May 16, 1920, xxxviii, 20. The modern history of this condition begins at about 1872 it having been experimentally produced by the injection of putrid matter. The association of virulent sepsis with gas gangrene was a puzzle for many years. Just before the war it had been accepted that several closely related conditions caused confusion—acute sepsis with gangrene at the wound focus, gaseous sepsis, nad gangrene septicemia. The nature of the wound was regarded as a factor and contusions, burns, and freezes caused a predisposition. The author cites old cases from civil practice in which the muscular system was quite exempt from trauma. The patient in one case was saved by amputation of a limb and the involvement of the muscle was found to be purely secondary. Other cases followed compound fracture, burn, etc. This series of cases was seen at Lille between 1889 and 1901 and no bacteriogical finds are mentioned. In summing them up the author states that in civil practice extensive osseous and muscular attritions with soiling of the wounds from without may cause gas gangrene in young vigorous subjects, so that cachexia is not a determining factor. Further in the absence of osseous and muscular attritions extensive compound fractures may cause gas gangrene or gangrenous sepsis of rapid course. Other wounds which may develop gas gangrene are deep burns and freezes. The author apparently includes gas phlegmon under gas gangrene. He believes he has shown that in civil practice we may see, although rarely, all of the forms of gas gangrene encountered in military practice.

News of the Week.

Drug Increase Attributed to Prohibition.—The Chief Inspector of the Vancouver Police Department is credited with the statement that the smuggling of forbidden drugs has doubled in Western Canada since the introduction of prohibition. During the last twelve months drugs valued at more than $300,000 have been seized and destroyed in the City of Vancouver. Figures compiled by the Board of Health of that city show the following increases in drug users in the last three years:

Drug.	1917.	1920.
Morphine	105	272
Opium	98	204
Heroine	134	416
Cocaine	92	308
Strychnine	0	69
Poisons in foods	10	16
Other identifications	11	118

Red Cross Magazine Suspended.—In consequence of the high price of white paper the American Red Cross has discontinued the publication of the Red Cross Magazine.

Hospitals Affected by Housing Crisis.—The United Hospital Fund has issued a statement to the effect that the shortage of apartments in New York City and the consequent increased congestion in living quarters are proving a menace to the health of thousands of persons who are unable to find suitable homes. Many families are unable to take care of their sick in their cramped quarters, and consequently the hospitals are overcrowded. In several of the leading hospitals twenty-five per cent. more private rooms are in use at present than at the corresponding time a year ago.

Profiteering in Rice in China.—On account of the high cost of rice in China millions of the inhabitants of the Celestial Kingdom are said to be on the verge of starvation.

Bubonic Plague in Paris.—Four cases of bubonic plague, with one death, have been reported in Paris.

Rat-Proof New York Urged.—In a lecture delivered recently at the Post-Graduate Medical School and Hospital Dr. Victor G. Heiser, who has just returned from an expedition to South and Central America, where he has been investigating bubonic plague under the auspices of the Rockefeller Foundation, emphasized the urgency of taking steps immediately to make New York safe from this disease. The beginning should be made at quarantine by the thorough fumigation of ships and the testing of rats every day. The city should be divided into zones and a well-organized rat campaign begun. The building laws should be amended to provide for a new method of construction which would render all new buildings ratproof. The same thing should apply to docks, so that the city would eventually become rat free.

Yellow Fever in Guatemala.—The appearance of yellow fever in two towns of Guatemala recently caused the suspension of passenger traffic and the institution of quarantine measures.

Straus Milk Stations Taken by New York City.—Eight Straus milk stations and the Straus Pasteurization Laboratory have been given to the city by Nathan Straus.

Insane Aliens Deported.—The annual reports of the Ellis Island Immigration Station and the New York State Hospital Commission for the year ending June 30, 1920, show that 290 insane aliens were sent from New York institutions to the countries from which they came. Of this number 147 were deported by the immigration authorities and 143 at the suggestion of Dr. Spencer L. Dawes, medical examiner of the State Hospital Commission.

Yellow Fever Increasing at Vera Cruz.—An average of five new cases of yellow fever a day was reported from Vera Cruz last week. All the patients are said to be young Spaniards who worked in commercial institutions. A force of five hundred workers has been given the task of covering all stagnant water near the city with petroleum in the effort to rid the community of the yellow fever mosquito.

Another Shaving Brush Anthrax Case.—A seventeen-year-old youth was taken to Bellevue Hospital a few days ago suffering from anthrax infection on the side of the face, believed to have been contracted from a shaving brush. He was given two injections of anthrax serum and it is thought that he will recover.

Alcoholic Wards Busy Once More.—According to Bird S. Coler, Commissioner of Public Charities, New York City, the number of persons treated in the alcoholic wards of Bellevue Hospital and Kings County Hospital, institutions to which all the city's alcoholic cases are sent, is fast approaching pre-prohibition size. The number treated at Bellevue Hospital will exceed 200 a month, it is said.

Medical Officers Wanted.—The United States Civil Service Commission announces competitive examinations for District Medical Officer, salary $1,800 to $3,000, and Assistant Medical Officer, salary $1,800 to $2,750. Applicants should apply for Form 2118, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the secretary of the local Civil Service Board.

Dr. Otto V. Huffman has resigned as member of the Faculty and as Dean and Acting Provost of the Long Island College Hospital Medical School. At its meeting held Aug. 10, the Board of Regents of the institution accepted the resignation. Dr. Huffman will move back to New York City where he will resume his private practice. He has been appointed a member of the Faculty of the New York Post-Graduate Medical School and Hospital and Chief of the Medical Clinic. The Deanship of the Faculty and the Provostship of The Long Island College Hospital are vacant pending the selection of Dr. Huffman's successor.

An International First Aid Congress.—According to Col. C. H. Connor, U. S. A., Assistant Director General of the Department of Military Relief of the American Red Cross, sixty-three First Aid teams, representing 17 States in which mining is numbered among the chief industries, have already sent their entry for the International First Aid contest to be held in Denver, September 9, 10 and 11. An international flavor is given the meet by the entrance of teams from the mining regions of Canada and Mexico, and additional entries from many States are awaiting the results of State elimination contests. The meet is being held under the auspices of the United States Bureau of Mines in cooperation with

the Bureau of First Aid of the American Red Cross. The American Red Cross will have charge of all judging of events and awarding of prizes. Dr. E. R. Hunter, of the Red Cross, has been selected as chief of judges with Dr. J. W. Amesse, of Denver, and R. Z. Virgin, of the *Coal Trade Bulletin*, of Pittsburgh, as his assistants. In addition to the bronze medal awards to members of winning teams in the First Aid events by the American Red Cross, prizes from mine owners and operators and hundreds of others interested in the advancement of First Aid work in mines will be given.

Obituary Notes.—Dr. CHRISTIAN F. J. LAASÉ of New York City was found dead in his study August 21. He was fifty-one years of age, and was graduated from New York University Medical College in 1894, specializing in surgery. He was attending surgeon at St. Mark's Hospital, of which he was also registrar, and visiting surgeon at St. Joseph's Hospital. He was a member of the American Medical Association and of State and local bodies. Dr. Laasé was recently acquitted in the United States District Court of the charge of the illegal sale of drugs. He was a man of high principles but of great sensitiveness, and the notoriety connected with his indictment and trial so played upon his mind that it is believed to have precipitated the cardiac trouble which was the direct cause of his death.

Dr. EDWARD WAGNER of New York City died August 14, at the age of fifty-one. He was graduated from the College of Physicians and Surgeons in 1891.

Dr. DANIEL P. MURPHY of Elmira, N. Y., died August 17, at the age of forty-six. He was graduated from the University of Buffalo, Department of Medicine, in 1902, specializing in surgery. He was a trustee of St. Joseph's Hospital.

Dr. FRANK CHURCHILL, New York City, died August 20, at the age of sixty-six. He was graduated from New York University Medical College in 1887, and specialized in ophtalmology.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 30, 1920.

Work of the Cancer Research Fund.—The eighteenth annual meeting of the Imperial Cancer Research Fund was held on July 22 last in London. Sir William Church, in moving the adoption of the annual report, said that Dr. Murray, the director, had continued the autologous grafting experiments on which he had been long engaged. They furnished the most conclusive evidence which could be obtained easily of malignancy or innocence of new growths. By transplanting an animal's own tumor to a part of its body away from the site of the primary growth an artificial metastasis was established. These inoculations, unlike transference to normal animals, succeeded in a high percentage of cases. It was to be hoped, therefore, that this method would be more widely applied as a control in the experiments on the experimental production of cancer by chronic irritants which were being undertaken in so many laboratories throughout the world. Sir William Church went on to point out that Dr. Cramer had examined the action of a number of inorganic substances on cancer cells. Salts of cerium were found to be the most active of those tested. Manganese and uranium salts were less potent. None of these substances, however, had any influence on tumors growing in the living animal. This was probably due to the irregularity of the circulation in the tumors, which delayed the access of the reagents to the cells. This was one of the difficulties constantly met with. The cancer cell was so like the normal cells of the body that agencies which destroyed it were also dangerous to life. Before a rational method of treatment could be planned it would be necessary to know more of the vital processes in cancer cells and the nature of the very delicate differences between them and the normal. Dr. Drew had approached the problem by studying the rate of decolorization of dilute methylene blue solution by normal and cancer cells. With this method there is a wide difference between the two, decolorization being much more rapid with normal cells. Dr. Russell and Dr. Gye had suspended the tissue emulsions in fully oxygenated defibrinated blood and measured the rate at which oxygen was abstracted on incubation at body temperature. By this second method the differences were much less pronounced, and it was found that the more rapidly growing tumors absorbed more oxygen than those which grew slowly. The investigations were being continued and gave promise that interesting light would be thrown on this fundamental feature of the life of cancer cells.

Keeping Disease Out of the Country.—The Ministry of Health has issued regulations recently extending and strengthening the powers of port and riparian sanitary authorities in connection with the prevention of the introduciton of infectious diseases into Great Britain. It is pointed out that conditions resulting from the war have given rise to increased prevalence of acute infectious diseases, such as smallpox and typhus fever, in certain foreign countries, and that the risk of the importation of these and other diseases into the United Kingdom through the agency of shipping renders it necessary that all practical measures should be taken to avert the danger. According to present plans it is not proposed to alter the cholera, yellow fever, and plague regulations of 1907. As for other infectious diseases, the minister is advised that the scope and character of the existing powers of the sanitary authorities are inadequate. The new regulations therefore confer further powers and impose additional duties upon such authorities and their medical officers of health, and require in certain circumstances, when the presence of infectious disease on a ship is suspected. A more extended medical examination of persons entering the country, than has been undertaken hitherto. Medical officers are empowered to board any ship for the purposes of the regulations, and to cause it, if necessary, to be moored or anchored in some safe and convenient place while it is visited and examined. They are also authorized to examine any person on board a ship who is suffering from infectious disease, or who is reasonably believed to be ver-

minous, or to hold the ship when there is reason to suspect that infection exists on board. For the purpose of the examination the medical officer may detain any person either upon the ship or at some appointed place on shore. In deciding whether he shall use his powers to board a particular ship and examine persons on board, the medical officer must to a large extent use discretion; but the Minister considers that the fact that a vessel during the period of three weeks before its arrival in port, has sailed from, or called during the voyage at, a foreign port or country in which dangerous infectious disease is known to be prevalent, will constitute reasonable ground for the necessary action being taken. Other provisions enable the medical officer to order the removal to hospital of any person suffering from infectious disease, and require the master of a vessel to notify the presence in his ship of mortality or sickness among rats. The necessary powers are conferred on port authorities to provide qualified assistance for the medical officer, and additional equipment in the shape of waiting rooms, disinfecting plant, hospital accommodation, and means of transport.

Quinine and Its Related Alkaloids in Pharmacology and Therapeutics.—At the meeting of the British Medical Association held recently at Cambridge there was an interesting discussion on quinine and its alkaloids and it was stated, what is already known, that the alkaloids of cinchona bark had been by no means superseded in treatment by quinine. Professor W. E. Dixon opened the discussion in question and drew attention to the relationships of hydroquinine, hydrocupreine, euquinine, cinchonine, and similar derivatives, to the mother substance. He went on to explain that the characteristic action of quinine on living tissues consisted in a reduction of general metabolism, and illustrated the relative strengths of the quinine derivatives in this respect by their action on protozoa and on bacteria and by their efficacy in producing paralysis of sensory nerve-endings in the cornea. The striking feature of the quinine derivatives was the relatively small concentration necessary to produce marked effects. **Major H. W. Acton told of the experience** he had had with cinchona alkaloids other than quinine in the treatment of malaria. Major Acton's experience showed that while quinine is useful in the treatment of malignant tertian malaria it exerts but little beneficial effect in eradicating benign malaria. On the other hand, the total alkaloids of cinchona act upon the latter form of malaria with excellent curative results. Professor J. A. Gunn said that he had experimented with the alkaloids harmaline and harmine, and had obtained encouraging results in cases of relapsing malaria. Dr. C. M. Wenyon said that very little new knowledge on the subject of quinine administration had been obtained during the war. The mode of action of quinine was very uncertain but useful light might be shed on the problem if the plasmodial infection in birds was further studied. It would be useful to know the reason why quinine produces so little effect in this case. As the Lancet of July 24 points out in an editorial the isolation of the active principles of drugs is not sufficient. In fact, with drugs as with foods, there may be a danger of over refinement. Taking from rice the vitamine element and possibly other elements by refinement of milling brings about beriberi in those living exclusively on rice. Scurvy also is due to the absence or inadequacy of a certain vitamine content of food. So it may be, and probably is, with drugs. In many instances the crude preparations yield better results in treatment than the active principles. Consequently, it is to jump at conclusions somewhat hastily to decide that it is always better to prescribe the active principles which give these drugs their properties than preparations of the raw drugs. The raw drugs may contain some properties of which we know not and which are appropriate for the treatment of certain conditions, or they may act in a manner best calculated to give the most satisfactory results.

Lister Memorial Fund.—It was mentioned in a previous letter that steps were being taken to raise a memorial to Lord Lister commensurate with the value of his medical scientific work. At a public meeting held at the Mansion House, London, in October, 1912, the following proposals for commemorating the work of Lord Lister were adopted: (1) The placing of a memorial in Westminster Abbey, to take the form of a tablet with a medallion and inscription. (2) The erection of a monument in a public place in London. (3) The establishment of an International Lister Memorial Fund for the advancement of surgery, from which either grants in aid of researches bearing on surgery or awards in recognition of distinguished contributions to surgical science should be made irrespective of nationality. A meeting of the General Committee of the Fund was held at the house of the Royal Society of Medicine on July 19 to receive and adopt the report of the Executive Committee appointed in 1912. The chairman, Sir Archibald Geike, stated that the sums received in respect of subscriptions from the British Empire and foreign countries amounted to £11,846.5.10. The report proceeded to state that delay had necessarily occurred in carrying out all the proposals adopted at the Mansion House meeting, but that a memorial tablet, executed by Sir Thomas Brock had been unveiled in Westminster Abbey on November 1, 1915, and steps were being taken for the erection of a monument in a public place in London. In order to carry out the scheme for the establishment of the International Lister Memorial Fund for the Advancement of Surgery the following proposals were adopted: (a) That out of the general fund a sum of £500, together with a bronze medal, be awarded every three years, irrespective of nationality, in recognition of distinguished contributions to surgical science, the recipient being required to give an address in London under the auspices of the Royal College of Surgeons of England. (b) That the award be made by a committee constituted as follows: Two members nominated by the Royal Society, two members nominated by the Royal College of Surgeons of England, one member nominated by the Royal College of Surgeons in Ireland, one member nominated by the University of Edinburgh, and one member nominated by the University of Glasgow. (c)

That any surplus income of the General Fund, after providing for the erection of a monument, and after defraying administrative expenses, either be devoted to the furtherance of surgical science by means of grants, or be invested to increase the capital of the fund. The continued carrying out of this scheme in future years will require the provision of some permanent and adequate machinery as the Lister Memorial Committee cannot, in view of its constitution, be itself permanent. The committee, having ascertained that the Royal College of Surgeons of England would be prepared to become the trustees and administrators of the Lister Fund and to carry out its objects, subject to the above provisions of the scheme, authorized the executive committee to take such steps as may be necessary to give effect to this arrangement. It may be mentioned that the subscription list is still open, and that the honorary treasurer of the fund is Sir W. Watson Cheyne, to whom donations may be addressed at the Royal Society, Burlington House, London, W.

SYNTHETIC SUPRARENINS AND THEIR DERIVATIVES.

(From Our Swiss Correspondent.)

GENEVA, Aug. 1, 1920.

Dr. F. Loup has completed a long and carefully conducted series of experiments with synthetic suprarenins and their derivatives and since his results have not appeared in the medical press an outline of his results may not be devoid of interest. He found that levogyrate, dextrogyrate and racemic suprarenins, as well as homorenon and arterenol—bodies very closely related chemically—have similar pharmacodymanic actions and hardly differ from each other except by the intensity of their action. When injected into the auricular vein of the rabbit in a 1 per cent solution they kill in doses of milligrams per kilogram of animal: left suprarenin 0.2 to 0.3; racenic suprarenin, 0.25 to 0.3; right suprarenin, 1.0; hormorenol, 6.0 to 7.0; arterenol, 0.25 to 0.3.

If we represent the toxic equivalent of left suprarenin by 1, that of racemic suprarenin will be about 1.25, right suprarenin 5, hormorenon 30, and arterenol 1.25.

It is interesting to note that only very little difference exists between left suprarenin and racemic suprarenin. Theoretically the activity of the latter should be represented by the arithmetical average of the activities of the dextrogyrate and levogyrate suprarenins, since the racemic bodies are regarded as the result of the combination—molecule with molecule—of two inverse optics.

Abderhalden and his coworkers admit that racemic suprarenin acts rather less strongly than its tenor in left suprarenin might lead one to suspect. These writers suppose that dextrogyrate suprarenin exercises an impeding action on the effects of levogyrate suprarenin and they reinforced the resistance of mice to left suprarenin by preventive injections of right suprarenin.

Loup's experiments carried out with rabbits, did not allow him to come to any like conclusions. He found that right suprarenin did not reinforce the animals' resistance while racemic suprarenin appeared to act as if it contained about 75 per cent. of left suprarenin. This fact may lead one to suppose that between the two isomers there exists not only quantitative differences, but qualitative differences as well that Loup's technique, likewise that of his predecessors, has been incapable of placing in evidence. Dr. Loup intends to repeat experiments on this point at a later date and in this respect it may be well to recall that Prof. Mayor of Geneva has shown that the two isomeric nicotines differ from each other, not only by the intensity of their action, but also by the modality of the action.

From the viewpoint of the therapeutic use of these various bodies, Loup's experiments permit of conclusions on only two points which are, firstly, the local action and secondly, the action of intravenous or intramuscular injections on the circulatory system. As to the local action it was found that left and racemic suprarenins—very strongly vasoconstrictive when in concentration which does not provoke any irritation—are far superior to other substances of the same group and that none of the latter can be employed with advantage over the former.

As to the cardiovascular action, Loup has shown that all these bodies are—activity being equal—quite as toxic as left suprarenin, so that they do not appear to merit any place in therapeutics. Perhaps an exception should be made in favor of hormorenon which, thirty times less toxic than levogyrate suprarenin, has nevertheless a sufficient action. We do not know, however, that the latter product has ever been used in man for raising the blood-pressure.

3. The Effect Upon the Blood Pressure of the Injection of Adrenalin in Dementia Præcox.—Lowrey and Wright, from an analysis of the blood pressure reactions to the injection of adrenalin in 78 psychopathic cases, consider it clear that it does not have the value in differential diagnosis which has been claimed for it, at least in early cases, since cases of precox show a rise and other cases show a fall. In 54 of 60 cases of dementia precox there was an increase in blood pressure, 40 of these showing rise of more than 5 mm. Hg. In 18 cases of other types taken for comparison there was a depressor reaction in four. The cases were carefully selected in order that these observers might be as certain as is clinically possible that the patients belonged to the groups stated.

1. Diagnosis and Treatment of Hyperthyroidism — M. H. Fussell describes briefly the laboratory methods

which help in the differentiation of hyperthyroidism and other conditions due to disturbance of the thyroid gland, referring to these as: 1, increased metabolic rate; 2, thyroid feeding; 3, adrenalin test, Goetsch test; 4, decreased sugar tolerance. He discusses the differentiation of hyperthyroidism in the presence of neurasthenia, irritable heart, tuberculosis, interstitial nephritis, gastrointestinal conditions, arthritis, local conditions of the eye giving rise to exophthalmos, and hypertrophic atoxic goiter. After discussing briefly the treatment of the different forms of goiter, including operative treatment, the writer gives the following succinct plan which may be followed in treating hyperthyroidism with the minimum of fatality: (1) An early diagnosis is imperative by the methods detailed. (2) Every patient should be put to rest in order to reduce the metabolism rate. Many patients will be cured by this means. (3) Patients who cannot give the time to a thorough trial of rest should be operated upon early, after a partial rest. (4) Patients who are very toxic must always be put at rest and given other appropriate treatment before any form of surgery is attempted. (5) If patients fail to improve under rest, ligation should be done, or the röntgen ray should be used tentatively to reduce the metabolism rate, until a resection can be done. (6) In very severe cases in which the patients appear to be approaching death, and the x-ray cannot be used, a ligation after the method of Wood may be done. In the writer's opinion patients who do not promptly respond to rest should be treated surgically.

4. Abdominal Symptoms in Influenza Simulating an Acute Surgical Lesion.—Thomas Hubbard Russell became interested in this subject through the personal observation of five cases of influenza presenting pronounced abdominal symptoms, sufficient in every case to have caused the possibility of an acute surgical lesion in the abdomen to have been entertained. Among the lesions known to occur in the abdomen secondarily to influenza are peritonitis; rupture of the rectus abdominis muscle; multiple abscesses of the kidney, and perinephritic abscesses; thrombophlebitis of the large abdominal vessels; general congestion of the intestines, with submucous hemorrhages; rupture of the colon. Some observers believe that there is a close relationship between appendicitis and influenza, but the writer does not consider the statistics convincing. From his study Russell concludes that abdominal symptoms which would ordinarily indicate the need of an urgent surgical operation are commonly present during influenza, and their frequency is not sufficiently brought out in the textbooks. Conditions requiring an abdominal operation during influenza or its convalescence are exceedingly rare. While in some cases a differential diagnosis is extremely difficult, the safest procedure in doubtful cases is to adopt an expectant treatment. In case an exploratory operation is decided upon, a local anesthetic is advisable. A surgical abdominal lesion and influenza may occasionally coexist. Many unnecessary and harmful operations have been performed during the course of influenza, due to the lack of appreciation of the frequency with which abdominal symptoms occur in influenza. The great majority of cases showing abdominal symptoms have no surgical basis, but are either reflex, or due to some condition which would not be benefited, but rather harmed by a laparotomy. The chest should always be carefully examined before operating for a supposed acute surgical lesion of the abdomen.

1. The Rôle of Deep Alcohol Injections in the Treatment of Trigeminal Neuralgia.—Harvey Cushing draws the following conclusions from his consideration of this subject: (1) Deep extracranial injections of alcohol into the maxillary and mandibular nerve trunks near their foramina of exit from the skull have completely superseded peripheral neurectomies. (2) In neuralgias limited to one or two lower divisions, and which may possibly not extend into the other trigeminal areas, alcohol injections represent unquestionably the treatment of choice. (3) When the neuralgia has spread beyond its original area and come to involve that supplied by the adjacent division, a trigeminal neurectomy must be contemplated; but if no preceding deep injection has been given it may be useful not only in insuring the type of the neuralgia but in giving the patient some warning as to what the numbness resulting from the neurectomy may amount to. (4) They are sometimes useful, furthermore, in determining in doubtful cases whether the syndrome is a true neuralgia of the tic douloureux type or one of the peculiar and rare psueudoneuralgias not amenable to relief either by injections or neurectomies. (5) Even the extracranial injections are not entirely free from risk, and in no cases should they be purposefully pushed to the point of attempting an injection of the gasserian sheath itself. (6) With such perfect and permanent results as may be secured to-day by a trigeminal sensory root avulsion, the prolonged and repeated use of injections in refractory cases which involve more than one division should be deplored.

2. Diagnostic Significance of Nerve Symptoms in Acute Infections.—Sir Thomas Horder deals with the subject from two points of view: (1) The general, or synthetical aspect, and (2) the particular analytical aspect. Under the first heading he considers briefly the mechanisms, physiological and histological, by which nerve symptoms in acute infections are produced; under the second he considers these symptoms themselves and their diagnostic significance.

5. Intrinsic Cancer of the Larynx.—Sir St. Clair Thomson holds that impaired motility of a cord is not a necessary or frequent symptom of intrinsic cancer of the larynx. It is, in fact, only met with in a minority of cases presenting themselves for diagnosis. It is more apt to be met with in an early case when the growth is embedded in the cord or growing into it in a distinctly sessile or even pedunculated tumor. It is also more usual with growths situated on the inner surface or the subglottic area than with those seated on the upper surface of the cord. Otherwise, fixation indicates an advanced case. When fixation is present it is a very valuable symptom in distinguishing a malignant from an innocent tumor. It is of little value,

and may even be misleading, in diagnosing a malignant growth from a tuberculous or syphilitic deposit. While in some cases it may be necessary to postpone a diagnosis in the absence of this symptom, yet, as it is desirable to avoid any delay, one may have to rely on inspection, the age, sex, history, and progress of the case, and the exclusion of other possibilities. The help of microscopic examination of a removed portion is available in only a small number of cases. This was the case in only ten out of the writer's forty-four cases. As regards prognosis, impaired mobility is an unfavorable symptom.

8. A Note on a Method of Treating Hay Fever and Paroxysmal Rhinorrhœa. Morley Agar.

1. Surgical Treatment of Gastric Ulcer.—Sir Berkeley Moynihan, in this opening paper before the Eighty-Eighth Annual Meeting of the British Medical Association, considers the surgical treatment of chronic gastric ulcer as offering the possibilities of gastro-enterostomy; excision; gastroenterostomy combined with excision by knife or by cautery (Balfour's operation); gastroenterostomy combined with jejunostomy; resection of a part of the body of the stomach—"sleeve resection"; partial gastrectomy. The different methods are discussed. For the purpose of illustrating his practice in connection with operations upon the stomach and duodenum Sir Berkeley has collected all the records of cases operated upon by him since 1909, including the years of the war. Every case of simple disease of the stomach or duodenum (excluding acute perforation) is included: cases of gastric ulcer, hour-glass stomach, duodenal ulcer, and jejunal or gastro-jejunal ulcer following upon gastroenterostomy. There were in all 835 operations upon 834 patients, with 12 deaths—a total mortality of 1.43 per cent. Excluding the cases of jejunal ulcer there were 808 operations on cases of gastric and duodenal ulcers, with 10 deaths—a mortality of 1.23 per cent.

Dr. Charles H. Mayo summarized his part of the discussion as follows: If it is true that the majority of the cases of duodenal and gastric ulcer have an average duration of a number of years, many extending from twenty to thirty years, it is probable that there is an exaggerated idea of their danger to life. Few persons die from perforation, and few from hemorrhage—more, however, than die from surgical procedures. It is true that they suffer, are disabled, and should be relieved; and it is also probable that but a small percentage of the total number of ulcers are recognized or treated for the true condition. Gastric ulcers may give greater discomfort than duodenal ulcers, and, because of the danger of malignant degeneration, should be destroyed at the time of the operation unless this procedure would add unwarranted immediate risk. He believes that patients who suffer from gastric ulcer should be told of this danger. In fact, the surgical treatment of ulcer is the best recognition of the value of medical treatment by permanently overcoming delay or obstruction and lowering the acidity with the patient's own alkalis.

2. The Diagnosis of Glaucoma.—Robert H. Elliot, after discussing the ophthalmoscopic evidence of an increase in intraocular pressure, mechanical tonometry, perimetry, examination of light sense, and measurement of the diameter of the cornea, made the following remarks of a practical nature: (1) In the observation of a case of glaucoma one must take into account the evidence obtained from scotometry, perimetry, tonometry, ophthalmoscopic appearances, and other physical signs, and from diminution in the visual acuity. A diagnosis should never be made on the strength of one feature of the case alone, if any shadow of doubt exists in the surgeon's mind. (2) If there is clear evidence that the disease is progressing, and that progress is due to an increase in tension, it is one's duty unhesitatingly to recommend an operation for the production of a filtering cicatrix, and to urge that this be undertaken at the earliest possible moment. If there is one point on which all the greatest authorities, from von Graefe onward, are agreed, it is that the earlier the operation is undertaken the better is the prospect of success. Not only will more sight be saved thereby, but the procedure itself is easier for the surgeon and safer and more certain for the patient. 3. It is idle to pretend that any operation for so serious a condition as glaucoma is devoid of anxiety, and both sides of the question should be set squarely before the patient. The risks of failure increase progressively in proportion to the delay, but against this is ever to be placed the fact that progressive glaucoma is a relentless disease, which ends in the majority of cases in total blindness. Even when central vision is lost at the time of operation—an ever-present danger in late cases—peripheral vision is often retained indefinitely, to the great advantage of the patient.

11. Ovarian Function Following Hysterectomy.—Edw. H. Richardson submits certain facts in support of two propositions: (1) that the uterus is not essential to a continuation of normal ovarian function, except as regards menstruation and reproduction, and (2) that the ovary possesses extragenital functions of paramount importance in the body economy, which are capable of operating quite independent of the uterus and which alone should suffice to insure its conservation whenever this is practicable. He summarizes briefly the scope and complexity of ovarian influence outside the genital domain, and then considers to what extent, if any, this influence is discounted through surgical removal of the uterus. From this study the writer is led to state, with emphasis, his uncompromising opposition to the teaching that ovarian function *in toto* is disrupted through surgical removal of the uterus, and to say that he believes such teaching, from whatever source, is dangerous and without scientific justification. He condemns the removal of one or both ovaries at any age simply because hysterectomy is required.

Influence of Diet on the Water Content of the Body.—Isenschmid states that the three months' fetus is 94 per cent. water, the newborn infant about 67 per cent., and the adult at least 60 per cent. If the body were boneless the per cent. would be 75. This water content in its composition represents the original water of the primeval ocean, which, however, is a somewhat more concentrated solution of the salts than is human

serum. The water content of the body is fluctuating in amount. As already implied, it is less in the adult than in the child and continues to decrease in old age. The initial loss in intrauterine life is rapid, while the older the subject the slower the rate of decrease. When we ingest a large quantity of water it is rapidly eliminated, while conversely the loss by transpiration is quickly made good. Sodium chloride in the diet favors water retention, and if a subject has lost much weight through training he regains it much more slowly on a salt poor diet. In subjects who have been deprived of water the first water drank is retained even in the absence of salt in the diet; but after the proper balance is struck it is reasonable to believe that increased salt in the diet makes for increased water retention and weight. This is due to the tendency of the organism to maintain a fixed ratio between water and chloride. Any amount of chloride over and above the concentration ratio is excreted. Salt poor diet is valuable in edematous affections, while foods rich in potash cause elimination of sodium and are also indicated in the same class of affections. The water intake in edema diseases must, of course, be restricted, while readily digested and ash poor food also unburdens the circulatory and eliminatory organs. Restriction of protein has the same result. The calory requirement should be sufficient, for inanition is a special cause of edema—the hunger edema so common in the late war. The two forms have been confused heretofore. Thus after typhoid and dysentery the edema which is sometimes seen is better explained by inanition than by cardiac weakness.

The Casoni Cutireaction in Echinococcus Disease.—Luridiana refers to the original attempt by Ghedini to diagnosticate this condition by the method of complement deviation. Weinberg is entitled to the credit of independent discovery, so that we may term this method the Ghedini-Weinberg. By using the Weinberg modification the percentage of positive results has been over 80. Other reactions were then introduced, including the intradermic method of Casoni, in which the antigen is the clear hydatid fluid obtained aseptically by puncture, filtered several times through close filters and preserved by adding a little phenol. Of this fluid half a cubic cm. is infiltrated into the skin with separate control injection of physiological serum. In about twelve hours one sees develop in positive cases an oval area of erythema which may reach the size of the palm. The trustworthiness is somewhat greater than in the complement deviation test, being 87.5, as against 83. Naturally the two may be used advantageously in the same case or rather should the cutireaction prove negative the complement deviation test may be added. But in the six cases cited by the author from his own practice the one negative result was not checked up in this way. Of the other five diagnoses there were confirmed by operation, while the other two were not subjected to operation. The fifth cases ended in death, and autopsy could not be obtained. In twenty cases of negative cutireaction in which diagnosis could be made by operation or autopsy echinococcus disease was absent.

Abortive Treatment of Boils and Carbuncles.—Pacieri states that when the cause of these affections was unknown it was necessary to treat them symptomatically by incision, etc. We know now that they are due to the action of certain microorganisms and there appears to be no reason why the latter may not be attacked directly and their activity inhibited to a greater or less extent. The idea of injecting deeply about the infiltration some antiseptic is by no means new, but thus far has led to nothing definite in practice. Since 1913 the author, perhaps influenced by the work of Grossich on the antiseptic powers of iodine tincture, has been experimenting with deep injections of this substance. In his official capacity as prison physician opportunities have not been lacking. In 1911 the author had attempted this treatment with carbolic acid, with unfortunate result, so that much care was advisable in the use of iodine. It was evidently necessary to make the injections as early as possible. A total of 2 c.c. was injected about the mass of a beginning carbuncle and on the next day this mass was somewhat more mobile and no larger. In another twenty-four hours the tumor had become distinctly smaller, and by the fourth day a complete cure was evident without a drop of pus having formed. This cure was a most brilliant one, but offered no guarantee that a great discovery had been made. No second opportunity was furnished until 1914, when the result was duplicated in a somewhat longer time—six days. In a third case the same result was obtained and in a fourth the result was slightly inferior to the preceding through the escape of a little pus. This case was a furuncle on the back of the hand. In the next case a furuncle appears to have been aborted and cured by the fifth day, while another boil was aborted and healed by the fourth day. The total number of cases given is eleven. The description of the technique is defective and it is not obvious by what means or how large an area of tissue the author infiltrates with the tincture. Half or two-third of an ordinary hypodermic syringeful of ten per cent. iodine is used for an injection. It is not stated whether the needle is fixed or moves during the injection.

Revue médicale de la Suisse romande.

Lethargic Encephalitis.—This number is devoted largely to various aspects of epidemic encephalitis. Cramer reports nine cases of the lethargic and thirteen of the insomnic form. The lethargic cases are divided into deliriant and nondeliriant forms, while the insomnic cases were all of the myoclonic type, and the majority were deliriant as well. Tutrettini and Piotrowski write on the effects of lumbar puncture, which they carried out in twenty-two of the twenty-five cases treated. They find a characteristic picture which is of value in diagnosis—albumin normal or slightly augmented, chlorides and tension normal, early lymphocytosis most marked in the oculo-lethargic cases and moderate and even absent at the début of cases of other types, diminution of lymphocytosis with regression of the disease, early augmentation of glucose. Puncture has no therapeutic value. Roch writes of the electric chorea of Dubini. He calls attention to the fact that there prevailed in Lombardy at the time of Dubini's paper another malady known as convulsivo-cerebral typhus, which was of the epidemo-sporadic type. This affection was recognized and named by Frua, who was one of the first to report cases of Dubini's disease. Whether Frua recognized the identity of these two affections does not appear from the author's text, but the name is preferable to electric chorea, which does not connote an acute febrile disease. Roch now gives in detail a case of myoclonic encephalitis which conforms very closely to the disease as seen by Dubini. The terms "electric" and "chorea" are especially well adapted to visualize the disease. Gautier writes on epidemic hiccough, which is lethargic encephalitis complicated by persistent diaphragmatic contractions. He narrates five cases of this type. Strange to relate, these spasms of the diaphragm were quite isolated and none of the cases were of the myoclonic type. Whether the hiccough is to be conceived as a monoclonus is uncertain. Dufour, who saw epidemic hiccough in Paris cases of encephalitis, records that one at least was of the myoclonic type, while Beclard saw cases with and without myoclonus. Fatal encephalitis with hiccough was seen in Berlin, and it is possible that fatal cases of hiccough known to have happened at intervals in the past may have been sporadic encephalitis.

Hospitals Are Supported by Lotteries.—In the Dominican Republic all the hospitals are supported by lotteries. Evidently the lottery business has not been overflourishing, for some of the hospitals are running at one-third of their capacity, according to the medical survey of that country recently made by the American Red Cross.

Book Reviews.

PRINCIPLES OF HUMAN PHYSIOLOGY. By ERNEST H. STARLING, C.M.G., F.R. S., M.D., Hon. Sc.D. (Cambridge and Dublin), F.R.C.P. Jodrell, Professor of Physiology in University College, London. The chapter on the Sense Organs Revised and Largely Rewritten by H. HARTRIDGE, M.A., M.B. Cantab. Third Edition. With 579 illustrations, 10 in color. Philadelphia: Lea and Febiger, 1920.

THIS work, since the appearance of the first edition in 1912, has become so well known to students and practitioners of medicine that little need be said of the present edition more than to call attention to the fact that it has been thoroughly revised in accordance with the advances made in physiology during the five years which have elapsed since the second edition was published. The principal changes involve the section on the Sense Organs, which has been revised and largely rewritten by Dr. H. Hartridge. The text, which embraces fifty pages more than the last edition, is arranged under four major divisions or books. The first, General Physiology, includes the structural basis of the body; the material basis of the body; the energetic basis of the body. The second, the Mechanisms of Movement and Sensation, covers the contractile tissues; nerve fibers (conducting tissues); the central nervous system; the sense organs. The third, the Mechanism of Nutrition, deals with the exchanges of matter and energy in the body (general metabolism); the physiology of digestion; the history of the foodstuffs; the blood; the physiology of the circulation; lymph and tissue fluids; the defence of the organism against infection; respiration; renal excretion; the skin and the skin glands; the temperature of the body and its regulation; the ductless glands. The fourth deals with the physiology of reproduction.

PRACTICAL DIETETICS, with Reference to Diet in Health and Disease. By ALIDA FRANCES PATTEE, Graduate Department of Household Arts, State Normal School, Framingham, Mass.; Former Instructor in Dietetics, Bellevue Training School for Nurses, Bellevue Hospital, New York City; Former Instructor at Mount Sinai, Hahnemann and The Flower Hospital Training School for Nurses, New York City; Lakeside, St. Mary's Trinity and Wisconsin Training School for Nurses, Milwaukee, Wis.; St. Joseph's Hospital, Chicago, Ill.; St. Vincent de Paul Hospital, Brockville, Ontario, Canada. Thirteenth Edition, Revised. Mount Vernon, New York: A. F. Pattee, 1920.

THIS is one of the best known works on Dietetics, it is also one of the simplest and least pretentious. It now appears in its thirteenth edition; so it has evidently met with the approval of physicians and nurses. The book has been revised so as to meet the requirements of the various State Boards of Examiners for Nurses; the author has also incorporated the latest researches in dietetics. Accompanying the volume is a pamphlet containing the requirements of the State Boards, and also examination questions from the various States.

MASS PHYSICAL TRAINING. For use in the Army and the Reserve Officers' Training Corps. By JOSEPH E. RAYCROFT, A.B., M.D., Professor of Hygiene and Physical Education, Princeton University; Member of War Department Commission on Training Camp Activities, and Chairman Athletic Division; Member of American Physical Education Association; Member of Society of College Directors Physical Education; Member of Athletic Research Society; Member of National Institute Social Science, etc. Foreword by W. G. HAAN, Major General, General Staff, Chief, War Plans Division. Washington: United States Infantry Association, 1920.

IN this volume of 282 pages the author has condensed into readable and available form the results of his unique experience in directing the physical and athletic training of millions of men to whom such matters were virtually unknown. With a corps of expert assistants familiar with every phase of physical culture and physical development, Dr. Raycroft spent months in experimenting with and testing out systems and schemes of training and instruction along the lines covered. The book, therefore, is a valuable addition to the literature of physical training. There are 147 figures and numerous diagrammatic illustrations of strategy and tactics.

PATHOGENIC MICROÖRGANISMS. A Practical Manual for Students, Physicians and Health Officers. By WILLIAM HALLOCK PARK, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College and Director of the Bureau of Laboratories of the Department of Health, New York City, and ANNA WESSELS WILLIAMS, M.D., Assistant Director of the Bureau of Laboratories of the Department of Health. Assisted by CHARLES KRUMWIEDE, JR., M.D., Assistant Director of the Bureau of Laboratories. Seventh Edition, Enlarged and Thoroughly Revised. Philadelphia and New York: Lea & Febiger, 1920.

THIS work began its existence as a small and unpretentious volume intended chiefly for the use of practitioners. It has grown through its seven editions to be what is practically the most complete and satisfactory one-volume bacteriology that is available to-day. The present edition has been revised in many respects, notably in the discussion of the subject of the hydrogen-ion concentration of media and of the bacteriology of the respiratory tract during the influenza epidemics. The bacteriology of war wounds and the recent work on the streptococci are among the topics that have been greatly elaborated in this edition. It is impossible to enumerate them all and it must suffice to say that the book appears to be "up to date" in every respect. The illustrations are numerous and very excellent. The text is clearly and attractively written and condensed as much as is possible with regard to clarity. In all it is the best work on bacteriology that is offered to-day to the student and practitioner and to the bacteriologist also who with it at hand will need only occasionally to refer to the encyclopedic works on the subject.

LABORATORY MANUAL OF PHARMACOLOGY. Including Materia Medica, Pharmacopœdics, and Pharmacodynamics. By A. D. BUSH, B.Sc., M.D., Professor of Pharmacology, University of North Dakota. Illustrated with full-page plates, many in colors. Philadelphia: F. A. Davis Company, 1919.

IN spite of its ungainly size, this book looks as if it might be very useful to medical students. It outlines the necessary Materia Medica, with the required laboratory work; and the student has his laboratory guide and his own note-book combined in one volume. One of the reasons why Materia Medica has always been unpopular with medical students is that the textbooks seem to have vied with each other in making the book as "comprehensive" as possible. As a result, every preparation of the pharmacopœia and several non-pharmacopœial preparations were included, with little or no indication as to the relative importance of the drugs. In the present volume this fundamental error is avoided, and a judicious selection has been made. There are a number of good illustrations showing the chief actions of the drugs; and the book is well arranged, and well printed.

NORMAL HISTOLOGY. with Special Reference to the Structure of the Human Body. By GEORGE A. PIERSOL, M.D., Sc.D., Professor of Anatomy in the University of Pennsylvania. Twelfth Edition. Philadelphia and London: J. B. Lippincott Co., 1920.

To those who are familiar with Piersol's work, no word of commendation is necessary. The present edition retains all of the desirable features of its predecessors and in addition has incorporated in it the advances that have been made in the subject since the appearance of the last previous edition. The section devoted to the consideration of each organ is headed with a paragraph upon the gross anatomy of the organ. This may be called superfluous by the critical but is nevertheless apt to be of much service. The illustrations are many and are exceedingly well drawn. Some of them are in solid color and it perhaps may be asked what advantage is possessed by such drawings over those in black and white. It would seem that they simply add to the expense of the work without improving it appreciably. But this is a minor detail and does not affect the value of the book. It can be recommended unreservedly.

Society Reports.

THE AMERICAN PEDIATRIC SOCIETY.

Thirty-second Annual Meeting, Held in Highland Falls, Ill., May 31, and June 1 and 2, 1920.

THE PRESIDENT, DR. THOMAS W. SOUTHWORTH OF NEW YORK, IN THE CHAIR.

(*Continued from page* 333.)

Dyspituitarism Socalled: Absorption of the Membranous Bones, Exophthalmos and Polyuria.—Dr. ALFRED HAND of Philadelphia presented this paper, in which he recalled a case which he had reported in the Transaction of the Pathological Society of Philadelphia, Vol. xvi, 1891-1893, under the heading "General Tuberculosis" and also in the *Archives of Pediatrics*, vol. x, 1893, under the title of "Polyuria and Tuberculosis." The patient was a boy, 3 years old, seen December 1, 1892, with a history of great thirst and polyuria of sudden onset eight weeks earlier. He had had enterocolitis at eight months and croup and measles at the age of two years. The family history was negative. The boy was undersized, with a dry, bronzed skin exophthalmos, corneal opacities in each eye and anterior synechiæ in the right. The thyroid was not enlarged. There had been rachitis. The urine had a specific gravity of 1.000 and the maximum quantity in twenty-four hours was 150 ounces, containing neither sugar nor albumin. After two months the boy died of bronchopneumonia, the main feature of the autopsy being a yellow area of softening in the right parietal bone involving both tables of the skull, with other areas affecting only the outer table. The kidneys were enlarged and the left had three small cysts, and in the pelvis of each was a hard, tuberculous mass; the lungs showed bronchopneumonia and there was small-round-celled infiltration of the liver, spleen and kidneys with degeneration of the epithelium of the uriniferous tubules. Dr. Hand quoted the notes of a case shown before the Medical Society of the State of Pennsylvania, in 1906, by Dr. T. W. Kay and reported by him as a case of acquired hydrocephalus, with atrophic bone changes, exophthalmos and polyuria. In the Osler Memorial Volume there was an article, "Defects of Membranous Bones Exophthalmos and Polyuria an Unusual Syndrome of Dyspituitarism," by Dr. Henry A. Christian, who reported such a case and had found two similar ones described by a German writer, Schueller. The latter said, "We can therefore make a presumptive diagnosis of anomaly of the skeleton as a result of disease of the hypophysis." Dr. Christian treated his patient with pituitrin which, when given under the skin and into a vein, caused great diminution in the amount of fluid ingested and excreted, but given by mouth or rectum it had no effect. Dr. Christian also concluded that the condition was due to disturbed pituitary function. To the above group Dr. Hand added a sixth case seen recently. The patient was a boy, four years of age, from whom there was removed at the age of two years a tumor-like swelling from the left parietal region; there was absence of bone beneath the tumor down to the dura. Section showed a slight degree of inflammation, but mainly a myxomatous change. Since then other swellings had appeared, and exophthalmos which was greater on the right, but as yet there has been no polyuria. Analysis of these six cases seemed to render the theory of dyspituitarism insufficient to explain the syndrome, although the polyuria undoubtedly depended on a disturbance of the hypophysis; the bone-changes seemed to be the primary condition, causing the exophthalmos mechanically by changes in the orbital plates, and the polyuria by changes in the sella turcica. The cause of the bone-changes was not clear and further observations were needed before this interesting and curious group of symptoms could be satisfactorily explained.

Use of Fresh Vaccines in Whooping Cough.—Dr. ROWLAND G. FREEMAN of New York presented this communication. He stated that two years ago he saw Dr. Hueneken's paper on the application of the complement fixation test for the detection of antibodies after injection of whooping cough vaccines, in which he showed that antibodies were not present unless the vaccines were freshly prepared and that after the vaccines were stored for a week but little antibody production resulted from their injection even in large doses. It seemed to him that this fact might explain the contradictory reports from the use of whooping cough vaccines in the course of their work, and he felt that it should be tried out. As he was unable to report any institution work he had brought together all the cases in which he had used the whooping cough vaccines in private practice, with the hope of stimulating interest in these fresh vaccines and thus rendering it easier to obtain them. This series of cases included 16 children with whooping cough in which the vaccines were used at various periods of the disease. In five no results were obtained, and of these three were early in the disease and the other two very late. In nine of the eleven remaining cases a very material improvement took place, and in four of these a practical cure was obtained. The quite remarkable results obtained in some beginning cases convinced him that these vaccines should have an extended use, particularly in institutions, where controls might be used to demonstrate whether we might not have in these vaccines a very valuable method of reducing the large mortality from whooping cough.

Dr. EDWARD J. HUENEKENS of Minneapolis, in response to an invitation to speak on this subject, stated that with the fresh pertussis vaccines one obtained from 90 to 100 per cent. positive complement fixation reactions; when the vaccines were four months old one obtained practically no positive reactions. The positive complement fixation reaction showed that the body was producing antibodies, but whether enough were produced to affect the pertussis was another question. If vaccines were used at all in whooping cough they should be fresh. Of the cases treated by vaccines, about 10 per cent. gave dramatic results; in another 10 per cent. there were practically no results whatever, while in about 80 per cent. there seemed to be a decided improvement, not dramatic, but sufficient to warrant their use. In St. Paul and Minneapolis it was now possible to obtain fresh pertussis vaccines on twenty-four hours notice.

Some Observations on Rickets.—Drs. JOHN HOWLAND and EDWARDS A. PARK of Baltimore made this contribution, which consisted in a lantern slide demonstration showing the alterations at the junction of the shaft and cartilage of the long bones in rickets as determined by the *x*-ray. A definite correlation between the *x*-ray signs and the pathological conditions was demonstrated. The proof was adduced that the calcium deposits in the cartilage cast well-defined shadows. The effectiveness of cod liver oil as a therapeutic agent in rickets was brought out by serial *x*-ray pictures taken during the period of its ingestion. In certain experimental animals a beginning calcium deposit could be demonstrated after the animals had been receiving cod liver oil for a few days. In human beings the calcium deposit in the cartilage was definitely demonstrable at the end of three weeks after beginning the administration of cod liver oil. Dr. Howland discussed the probable relation of cod liver oil to the process of repair.

Dr. GERSTENBERG of Cleveland said Dr. Howland made the eradication of rickets seem possible. They had fed 1,200 babies or more on a synthetic milk, containing 10 per cent. fat in the form of cod liver oil, and they had yet to see the first case of spasmophilia or rickets among the children so fed. Their idea had been to incorporate the cod liver oil in the food and thus prevent rickets.

Dr. CLIFFORD C. GRULEE of Chicago said that Dr. Femster had been making observations on normal children, feeding phosphorus, and by this means he had been able to produce a thickening of the ends of the bones very much the same as that produced by the cod liver oil. They had noted that with a longer feeding of phosphorus there was a greater thickening at the epiphyseal line. In these children the phosphorus was used alone and not in combination with cod liver oil.

Dr. HOWLAND said he and one of his associates had done work in which they had studied the phosphate content of blood after feeding cod liver oil and had

found it greatly increased. What brought that about he could not say. In one case in which they had found 1½ mgs. inorganic phosphorus per 100 c.c. of blood, after feeding cod liver oil they had found 16 mgs. of inorganic phosphorus. That result had been duplicated in other instances. This was a subject that needed further investigation. It seemed that cod liver oil had something to do with the utilization of phosphorus.

The Argonne Association.—Dr. ROYAL STORRS HAYNES of New York gave a lantern slide exhibit illustrating the work of the Argonne Association in France and described the method they were using in caring for dependent children. The work, he said, was divided into three sections, the first section being devoted to the care of children under four years of age, the second to those between the ages of four and fourteen years, and the third to vocational training for those over fourteen years of age. Children under four years of age were cared for in foster homes under the supervision of a visiting nurse and a medical director. The principle upon which the work was being conducted was that the proper care of the dependent child should carry him under one control until he was able to merge a self-sufficient citizen. In carrying out this plan an endeavor had been made to provide for every need of the growing child, physical, mental and moral, and in choosing a vocation the individual aptitudes of the children were studied and that occupation selected in which each would be happiest and most useful. The plan had been found most valuable in France and was described in the hope that it would be adopted for the care of dependent children in America.

Sarcoma of the Kidney.—Dr. ROWLAND G. FREEMAN of New York reported the case of a child 2½ years old, weighing 26½ pounds, who when she came under observation had been failing for two months. The diagnosis of tumor of the kidney was made and confirmed by *x*-ray. The tumor, a sarcoma, was removed and six weeks later the child was brought back to the hospital in a desperate condition. The *x*-ray showed numerous metastases in the lungs.

Focal Infections in Children.—Dr. OSCAR M. SCHLOSS of New York presented this report which concerned cases of focal infection of the tonsils which were responsible for two types of disturbances. In one group of cases the disturbances were cyclic in character, accompanied by fever and persistent vomiting with a large elimination of acetone bodies in the urine and an accumulation of acetone bodies in the blood. The other group presented a type of disturbance evidenced by milk nephritis. The urine contained albumin in moderate amounts, red blood cells, hyaline and granular casts and some leucocytes. These children were not especially ill. The symptoms were traced to tonsillar infection and subsided promptly when the infected tonsils were removed. Two such cases were observed. In the majority of cases in both groups, the tonsils were not large and in several instances had been removed leaving only a small amount of tonsillar tissue between the faucial pillars.

Hypertrophic Stenosis; Failure of Gruel Feeding; Operation; Slight Improvement.—Dr. H. M. MCCLANAHAN of Omaha presented this paper, in which he described his experience with six cases of hypertrophic stenosis coming under his care since June, 1919. Four of the six cases recovered under thick gruel feeding by the method described by Sauer and later by Dr. Langley Porter. The rate of gain varied; all, however, made slow but steady improvement. A fifth baby made fair progress for two weeks, but the parents, seeing the results in another case, demanded operation. He believed this baby would have recovered without operation. The sixth patient was in a serious condition at the time of operation, the walls of the stomach being dark in color. The infant had in addition to congenital hypertrophic stenosis, a general staphylococcus infection, and acute gastritis. This case would undoubtedly have terminated fatally without operation.

A Case of Portal Thrombosis.—Dr. RICHARD M. SMITH of Boston reported this case because of the rarity of this condition in children. He stated that the striking points in the case were the persistent fever, the enlarged liver and spleen, engorgement of the superficial abdominal veins, severe anemia, and intestinal hemorrhage. No diagnosis was reached during life. At autopsy thrombosis of the portal vein and its great radicles was found, with passive congestion of the spleen, hypertrophy and dilatation of the heart, edema of the lungs and anemia. Undoubtedly the thrombosis was of infectious origin arising in connection with an infection of the respiratory tract of which the child gave a history at the time of admission to the hospital.

A Case of Paralysis of the Respiratory Muscles.—Dr. W. MCKIM MARRIOTT of St. Louis reported this case, which was interesting because of the treatment applied. The patient was a girl, 10 years of age, who six weeks after a severe attack of diphtheria developed paralysis of the palate, ocular muscles, legs, back and neck muscles, and partial paralysis of the arms. Ultimately the diaphragm became involved, so that it failed to move at all during inspiration. Later the intercostals began to lose their power and the child became cyanotic and semi-comatose. She was obviously dying of suffocation. It was thought that if the respirations could be maintained for a sufficient length of time to allow for restoration of function of the respiratory muscles, recovery might be possible. Artificial respiration was given by means of the Erlanger-Gessel air current interrupter connected with a nitrous oxide mask. The child failed to co-operate at first, but later it was possible to get her to open the glottis at the right time so that air could be forced into the lungs at a regular rate. The effect was immediate. The cyanosis was relieved and after ten minutes the child fell asleep and the mask was removed. When cyanosis again developed artificial respiration was again resumed. This was kept up more or less continuously for five days, at the end of which time the function of the respiratory muscles began to return. The child was soon able to breathe without an apparatus and made a good recovery.

Congenital Atresia of the Esophagus.—Dr. HENRY L. K. SHAW of Albany reported this case, his object being to call attention to the historical side rather than to the clinical. He said the infant gave a history of the food coming out of its nose An attempt to pass the stomach tube failed. After giving barium, the *x*-ray showed the esophagus filling, but the barium did not pass into the stomach. The lungs were found filled with fine râles. The child died and at autopsy it was found that the esophagus ended in a cul-de-sac. The lower end of the esophagus had no relation to the upper end but terminated in a small opening into the trachea. There had been some 150 cases reported in the literature in 80 per cent. of which the anomaly was similar to the case described. A similar case had been described in 1682 and another in 1703 by a Dr. Gibson, Physician General to the British Army, and a grandson of Oliver Cromwell. Dr. Shaw read this description which was so accurate that it would be difficult to improve upon it to-day.

Dr. CLIFFORD G. GRULEE of Chicago said he had had the rather unusual experience of seeing four of these cases. Three of them were operated upon and died; not so much because of inanition as from hemorrhage. The tendency to hemorrhage in these cases seemed to be very great. Whether this was merely the increased tendency to bleed that seemed natural to the new-born or whether there was some other reason for it he could not say. The anomaly in each of these cases was different; one case, however, was very similar to the case reported by Dr. Shaw.

Dr. WALTER R. RAMSEY of St. Paul showed an *x*-ray picture which illustrated the exact condition Dr. Shaw had described.

Primary Sarcoma of the Thymus.—Dr. L. EMMETT HOLT of New York reported this case, occurring in a six months old child. This child's family history was negative. She had gained weight slowly, weighing 9½ pounds at the age of six months. The only symptoms exhibited were increased pallor and slight fever. There were minute hemorrhages over the neck and extremities. The case was looked upon as one of extreme secondary anemia. Hemorrhages continued to appear and blood transfusion was given without permanent benefit. At autopsy a thymus weighing 36 grams was found; the upper limit of weight for the normal thy-

mus was 10 grams. Sarcomatous changes were also found in a lymp node and in the spleen and lungs. The case was interesting because of the fact that the child exhibited none of the symptoms associated with enlarged thymus, and because of the rarity of sarcoma of the thymus in children.

A Case of Cardiospasm.—Dr. GODFREY R. PISEK of New York reported this case for the reason that the condition was still rare in early life. This patient, he said, was a girl, 12 years of age, whose family and past history were negative with the exception of the fact that the child was wilful and "temperamental." She gave a history of having had a choking sensation at times for a year. Moderate dilatation was done but no anatomical basis could be found for the trouble. She was finally sent away from home and improved for a time, but then contracted "malaria," lost weight rapidly, and the original symptoms of cardiospasm returned. She then returned home, was again given a thorough physical examination. Bougies were passed every four days, and she was given atropine and a measured diet. Under this treatment she was improving and it was still a question whether the duodenal tube would have to be passed and the stomach given a complete rest. The case showed that it was not so easy to treat the condition as one might be led to suppose from the literature.

A Case of Lymphosarcoma.—Dr. CHARLES A. FIFE of Philadelphia reported this case. He stated that the patient, a boy 9 years of age, gave a negative history until his seventh year when a slowly enlarging right cervical lymph node was detected. Notwithstanding the removal of tonsils and adenoids, the gland in ten months attained the size of a large egg. Supposing that the lesion was tuberculous, though the child gave no other evidence of tuberculosis, the gland was treated by the *x*-ray and radium. After twenty treatments, covering fifteen months, the disease was thought to be eradicated. The boy was in apparently perfect health for a third of a year, and then for five months before coming under observation had attacks of fever with remission. When he again came under observation he had a marked anemia; his heart was completely displaced to the right; liver and spleen enlarged, and a a mediastinal mass displaced to the right. A quart of amber fluid was removed from the left pleura after which the heart returned to its normal position. Within forty-eight hours the chest refilled. *X*-ray treatment and blood transfusion failed to stop the course of the disease. The child died about six months after coming under observation. The post mortem diagnosis was small and large celled lymphosarcoma. The structures involved were the cervical, tracheobronchial and retroperitoneal lymph nodes, the spleen and the liver. The chief histological interest lay in the fact that the nodes low down in the abdomen, where they were unaffected by the *x*-ray and radium treatment, were full of typical, active tumor cells, while the lymph nodes in regions treated by radiation showed retrograde changes in the tumor cells and many tumor cells were replaced by dense connective tissue.

Heart Displacement Apparently Due to Mediastinal Emphysema Following Aspiration Pneumonia.—Dr. E. C. FLEISCHNER of San Francisco reported this case. The patient was a boy, 3½ years of age, who following a fall in a sand pile became wheezy. Four hours later when brought to the hospital he had sibilant râles over the lungs both anteriorly and posteriorly. The *x*-ray showed no foreign body and no condition calling for surgical interference. The boy developed a definite pneumonia involving the middle lobe on the left side, and at the end of forty-eight hours a subcutaneous emphysema appeared above the clavicle and extended down to the pelvic bone. The heart was completely displaced to the right. The pneumonia subsided to be followed by a bronchiectasis in the left lung. A prolonged illness ensued from which the boy had finally made a good recovery. *X*-ray plates taken six months after the injury showed an apparently normal condition of the chest. It seemed reasonable to believe that at the time of the accident the boy had received an injury which had permitted air to escape through the lung into the mediastinum, to push the heart to the right, and then to work its way out into the subcutaneous tissues.

Streptococcic Angina with Purpura Hemorrhagica and Multiple Infarcts of the Skin and Subcutaneous Tissue in a Child Two Years Old, Healing Under Dakin's Solution.—Dr. WALTER R. RAMSEY reported this case which occurred in a child 2½ years old, whose present illness began with a sore throat two weeks before he came under observation. At this time he was practically moribund. The skin and mucous membranes were extremely pale; there was marked edema of the fact, feet and legs; numerous petechial areas were scattered over the body; the fauces and tonsils were covered with a foul gray membrane, and the entire mucous membranes of the mouth, including those of the lips, were gangrenous. The temperature was 104° F., and the pulse was rapid and weak. As the condition was suspicious of diphtheria, 20,000 units of diphtheria antitoxin were given immediately. The culture, however, proved negative. Under this treatment the purpura cleared up, but deep sloughs developed within a few days on the right wrist, on both ears, both elbows and the perineum. The palate sloughed off, and the middle phalanx of the middle finger on the right hand sloughed out. An area in the occipital region sloughed out and part of the bone also. All of these areas healed under Dakin's solution applied at hour intervals.

Report of a Case of Anaphylaxis Following an Intradermal Protein Sensitization Test.—Dr. HENRY J. GERSTENBERGER of Cleveland reported this case which presented the following points of interest: A boy 17 months old who had never received egg in any form developed an extreme anaphylactic shock after an intracutaneous administration of egg yolk allergen and egg albumin in doses of 1 and 2 mg. This child had received cows' milk from the third week of life and had suffered from eczema and asthma. He gave a negative intracutaneous test to cows' milk casein and cows' milk albumin. The intracutaneous injection of cows' milk allergen responded within twenty-four hours with an indurated and red area of infiltration not unlike that of an ordinary positive von Pirquet reaction, but entirely different from an urticarial wheal. The boy was not sensitive to other proteins. A first severe anaphylactic shock did not prevent a second five days later following the injection of egg yolk allergen. The *x*-ray photographs made at different intervals on the same day showed a definite wide abnormal thymic shadow and again a perfectly normal picture. The former, as found by fluoroscopic examination, occurred during extreme expiration, the latter during extreme inspiration. The thymus gland if it really were large in an abnormal sense did not produce the respiratory difficulty in a mechanical way. Dr. Gerstenberger suggested that this might be a case of status lymphaticus and that this condition might be responsible for the congenital pathological sensitiveness to egg proteins and the anaphylactic reaction. If, however, the child was found not to be sensitive to other proteins, especially horse serum and horse-hair protein, the status lymphaticus could hardly be accepted as a causative factor in his condition, for it would be difficult to imagine how a status lymphaticus could make a child sensitive solely to egg protein and not to oats, milk, horse serum, or horse-hair proteins. The anaphylactic shock after the injection of the egg albumin was so severe that had not adrenalin been administered immediately and artificial respiration employed the child would probably have died. Three c.c. of adrenalin was administered subcutaneously in divided doses—1 c.c. and then 2 c.c. These tests should never be made without having adrenalin at hand. If this precaution was always exercised he felt that fatalities due to anaphylaxis might be avoided.

Blood Findings Five Years After Splenectomy.—Dr. HOWARD CHILDS CARPENTER of Philadelphia presented this report. The patient was a boy, 10 years of age, who had had his spleen removed five years before for familial hemolytic icterus of the Chauffard-Minowski type. The result was satisfactory and the case was reported in the literature a few months later. During the past six weeks thirteen complete blood examinations were made, the average result of which showed hemoglobin 82 per cent.; red cells 4,288,000, and white cells 15,000. Prior to the operation the hemoglobin was as low as 23 per cent. and the red cells were down to

2,020,000. No Howell-Jolly bodies were found. Evidence of marrow regeneration was still present as shown by the high color index, the continued leucocytosis, moderate chromophilia and poikilocytosis, high transitional and eosinophile counts, and reticulation of the erythrocytes. There was an unusually quick coagulation time in spite of a rather low platelet count, indicating in this case either a rapid availability of the platelets for the purposes of coagulation or an increased amount of prothrombin in the platelets, or a large percentage of macroplatelets. The low platelet count was simply the continuation of the condition which existed before the splenectomy, as it was well known that cases of hemolytic icterus showed low normal values, sometimes even less than 200,000. An absolute lymphocytosis was found which was evidence of lymphatic activity, and this activity was also shown by the enlargement of the external lymph glands and the very large tonsils revealed on physical examination of the patient.

Dr. J. P. CROZER GRIFFITH of Philadelphia emphasized the fact that this paper was exceedingly valuable at the present time in view of the recent statement in the literature that in spite of splenectomy fragility of the cells continued. The paper showed that fragility did *not* continue and that was a very valuable point.

The Duct Sign in Mumps.—Dr. DAVID MURRAY COWIE of Ann Arbor read this paper, in which he recorded that 96 per cent. of 57 hospital cases of parotid mumps revealed the presence of a red spot at the orifice of Steno's duct, which developed and disappeared under the influence of the disease. The duct itself became teatulated. A number of cases were cited illustrating the way in which this sign developed and disappeared. It was observed that the sign appeared early in the disease, sometimes ahead of the swelling of the parotid and disappeared when the gland returned to normal. The degree of fever seemed to have no effect upon the degree of swelling and redness of the duct. The submaxillary ducts showed no redness when the submaxillary glands were involved. Whether the duct sign was pathognomonic of specific parotiditis or was present in other inflammatory conditions had not been determined. Owing to the fact that teatulation and redness of the orifice of Steno's duct occurred in a certain percentage of normal persons, careful differentiation must be made. The sign should be regarded merely as corroborative evidence of parotid gland involvement.

Dr. FRITZ B. TALBOT of Boston said he had observed the same sign but it required a very good light in order to detect it.

Dr. HEHRY HEIMAN of New York recalled having seen this sign described years ago in the old textbooks.

Dr. LANGLEY PORTER of San Francisco said this sign had been used by clinicians before. It enabled one to differentiate between suppurative parotiditis and ordinary infectious parotiditis. The color of the everted mucous membrane in infectious parotiditis was bright red, while in suppurative parotiditis it was a grayish-pink.

Dr. FREDERIC W. SCHULTZ of Minneapolis recalled having observed the duct sign among negro troops. He thought it was present in about 50 per cent. of the cases. In this connection he mentioned that the contagious period of mumps was longer than was usually given in the textbooks. It was fully twenty-one days, though the books did not give it as this long.

A Case of Priapism Resulting from Rapidly Spreading Malignant Myxosarcoma with Generalized Metastases.—Dr. DAVID MURRAY COWIE of Ann Arbor reported this case. The unusual feature of the case was the early age of the boy, nine years.

Further Development of Infants' Hospital.—Dr. HENRY I BOWDITCH of Boston made this contribution, in which he stated that the present-day tendency was to bring the scientific and laboratory side of the hospital into closer connection with the clinical side. This idea was being exemplified in the "On Shore" Department of the Boston Floating Hospital, a small hospital worked out on the basis of a ten-bed clinic. Three small adjoining apartment houses had been purchased and remodeled at a cost of $45,000. The scientific laboratories, chemical and bacteriological, were brought into close proximity, making consultation easy. The clinic was held in two wards and an isolation room, under the expert care of three nurses. The wards were so divided as to secure quiet, so that the children were able to have perfect naps morning and afternoon. As a result of this arrangement symptoms dependent upon restlessness, vomiting, etc., were markedly decreased. The clinic was so manipulated as to give five new patients monthly, or 60 a year. The plan was to have the patients return at definite periods for chemical and bacteriological tests, and physical and mental examination, for a period of ten years. In this way they would be able to follow the development of body and mind. On Tuesday afternoon of each week a health clinic, composed of 150 families, was held under the direction of an assistant visiting physician. This allowed the personal touch to impress the parents with the importance of physical care, proper dietetics, and discipline. On Wednesday a return "family control" clinic was held in charge of a visiting physician. Two clinics were also held for weighing the children, getting clinical histories, and giving treatment. Since the opening of the hospital on December 15, 1919, 30 patients had been treated, 23 of which were diagnosed as regulation of feeding and malnutrition in different degrees. It was the plan to admit only nutritional cases, infection being carefuly guarded against. The study so far had been to organize methods of attacking the question of the different food elements in growth and lack of growth. It was hoped that this beginning might lead others to establish similar "small enough" institutions, where each case could be completely examined clinically, chemically and bacteriologically, and carefully followed up, and which would serve as an educational center for parents leading them to a better understanding of the needs of child life.

The Effort Syndrome in Children and Young Adults.—Dr. CHARLES GILMORE KERLEY of New York read this paper, in which he reviewed the characteristics of the condition to which Dr. Thomas Lewis had applied the term "effort syndrome" and which was described by Friedlander and Freyhof as "constitutional neurocirculatory asthenia." The boy or girl who might qualify for this group came to the physician with the typical story, which condensed to its briefest terms, meant that there was an absence of capacity for sustained effort, both mental and physical. Wherever endurance was required this type of individual failed. In girls these constitutional peculiarities might attract less attention and be more readily excused when present. Among animals those of defective capacity for economic reasons soon perished. The defective functioning human, however, especially if well-born was urged and forced and stimulated to accomplish what was not in him. Millions of dollars were wasted on youths who were physically and mentally unable to meet the standard set up by ambitious parents and friends in an effort toward their so-called higher education. At the same time the highly trained teaching talent of our preparatory schools and universities was wasted in part on poor student material, 25 to 50 per cent. of which should be scrapped and put to productive occupation. Before a boy was permitted to avail himself of unusual educational advantages, it should be determined whether he was worth it. In addition to mental attainments required for college entrance, it should be required that a candidate submit testimonials as to physical fitness and mental capabilities from the head-master or high school principal. Expert diagnosticians were needed who would aid in placing boys at work for which they were fitted. The boy who belonged to the class under discussion should leave school at the age of fifteen or sixteen and take up business. The occupation should be one that was not strenuous if the boy was to make a reasonable success. It was unusual to find persons of this type the offspring of young vigorous parents. In the majority of instances they were the offspring of the weakly woman of little resistance and of lessened endurance capacity. A strong, vigorous mother would do much to offset the influence on progeny of a weakly male. The progeny of vigorous males was greatly impaired by inferior mothers. In some instances frequent child-bearing had apparently been a factor. These facts pointed to the necessity of paying a great deal of attention to the phy-

sical development of those who would some day be mothers.

Food Requirements of Children After the First Year.—Dr. L. EMMETT HOLT of New York presented this communication, which gave the results of an attempt to estimate the total caloric needs of healthy children over one year of age. This total was determined by an estimation of the four factors which made it up, namely: Basal requirements; needs for growth; needs for activity; loss by excreta. The per kilo requirement diminished steadily from one year to the completion of growth. Growth needs were calculated from the rate of increase in height and weight for the different years; these were naturally greatest at periods when growth was most rapid. The loss in excreta at all ages was practically 10 per cent. of the calories taken. Though subject to individual variation in different children, these three factors were as averages uniform and irreducible. The only factor which differed greatly in different children was the need for activity. A child of average activity used up nearly one-half his caloric intake in this way, while the very active child used up a much larger proportion of his caloric intake. The total caloric needs for the average child were greatest during the period of most active growth. This period for boys was between 15 and 17 years; for girls between 13 and 15 years. In this period the caloric needs exceeded those of adults with moderate activity of both sexes. The average adolescent boy required 4,000 calories daily. For boys the average per kilo need was 100 calories at one year; this gradually fell to 80 at six years. It then remained practically constant until 16 years, when it gradually fell until 19 years when it reached the adult average. In general, a little more fat, a little more protein and a little less carbohydrate was required by the child than by the adult.

The Misuse of Milk in the Diets of Infants and Young Children.—Dr. B. RAYMOND HOOBLER of Detroit read this paper, in which he asserted that there was much propaganda by popular writers urging the increased use of milk as a food for the young. He believed this was being overdone and that mothers were forcing milk in such quantities on their children that it became positively a menace to health. The dietetic errors made in this way might be classified under the headings: 1. Prolonged use of milk as an exclusive article of diet. 2. Increased quantities of milk given along with other foods. In addition to these errors the nutritional value of milk might be impaired by boiling. For various reasons the use of boiled milk was becoming more prevalent than formerly, and many injuries to nutrition occurred such as tetany, rickets, and scurvy, together with marked constipation. Charts were exhibited showing the diets usually fed between the ages of nine and twelve months, between one and two years, and between three and five years, and the relative proportion of the day's calories supplied by milk when one quart was fed. This showed that between the ages of nine and twelve months 80 per cent. of the calories were supplied by milk; between the ages of one and two years 58 per cent., and between two and five years 50 per cent. It was shown that when one quart of milk was fed in addition to other foods, the fat proportion was relatively high and the carbohydrate relatively low. The degree of overfeeding above the basal metabolism that took place under these conditions was also shown. When so much milk was fed the child frequently refused other food, and this habit robbed him of the minerals which should come to him in fresh fruits, vegetables, and cereals, not to mention the vitamine and antiscorbutic properties which these foods possessed. In contrast to this a second chart showed the caloric value and proportion of the food elements that were fed at the different ages when one pint of milk was given in addition to other foods. This demonstrated that by this kind of a diet the calories were reduced to within normal requirements, and the proportion of fat and carbohydrate were nearly interchangeable, thus giving the child ample calories to use in his activities. By giving only one pint of milk daily in addition to other food the protein intake was cut down to the maximum for growth, wear and tear. Children fed a well balanced diet of this kind were free from vomiting, stupor and acetonuria so prevalent in children who were receiving a quart of milk in addition to a full diet. The probaganda advising the feeding of a quart of milk daily was fallacious. If followed it led to over-feeding, an unbalanced diet, unhealthy nutrition and frequent attacks of vomiting accompanied by acetonuria.

Dr. CHARLES GILMORE KERLEY congratulated Dr. Hoobler upon having the courage to come forward and place the capacity of the child in its true light. He gave milk to the amount of only one pint daily after the child reached the age of fifteen months. The child fed entirely on cows' milk was likely to be flabby, and in the second, third and fourth year to have secondary anemia. The children which Dr. Hoobler mentioned as showing recurrent vomiting, and acidosis, were showing an incapacity for fat metabolism, or an inability to take care of a large amount of fat in addition to other foods.

Dr. THOMAS S. SOUTHWORTH of New York took exception to the statement that feeding boiled milk caused rickets, scurvy, and tetany. He thought the impression should not be given that the causation of these conditions could be so easily explained. Many of them believed that another factor was concerned in the production of these diseases. In the agitation for the larger use of milk, the fact that the kind of milk used was important had often been forgotten; it should be milk free from pathogenic bacteria.

Dr. E. W. SAUNDERS of St. Louis, put himself on record as agreeing with Dr. Hoobler in every respect. He recalled a paper on the ill effects of milk read four years ago, and said he wished to reaffirm the statements then made with additional emphasis. It was a mistake to raise the temperature of milk above 140° F., since that temperature served to destroy all pathogenic bacteria. If milk was raised to the temperature of 165 or 170° F. it would then be boiled.

Dr. L. EMMETT HOLT expressed the opinion that it was a mistake to go from one extreme to the other. In New York, he said, children as a class had been suffering from too little milk rather than from too much, due to the increasing price. He hoped the impression would not go out that they were feeding too much milk. He agreed, however, that a child who had eaten a hearty meal and then drank a glass of milk was being overfed; this glass of milk might be the last straw that acted as a factor in the production of a digestive disturbance. It did not follow that because milk was not a perfect food for a child two years of age it should be done away with altogether.

Precipitins for Egg Albumin in Stools.—Dr. CLIFFORD G. GRULEE of Chicago presented this study. He said that the preparation of the stools in this series of cases was the same as that reported in a previous article. The first series tabulated consisted of 100 stools from 21 cases which showed three positive reactions; in each instance the child had received egg-white in the diet. In a second series of 242 stools from 33 patients, there were five positive reactions. In this group some of the cases giving positive reactions had no egg albumin in the diet. It would seem from these results that egg albumin was in nearly every instance completely broken down by the digestive processes in infants and children. This held good not only for older infants and children but also where egg albumin was used in small quantities for the new-born as well. There was only one other possibility and that was that the egg albumin instead of being broken down in the process of digestion was absorbed unchanged. He did not feel that the specificity of the precipitin reaction for egg albumin was to any degree disproved by the fact that it was found to be positive in stools in which no egg had been present in the diet. He was inclined to attribute such reactions to the complexity of the stool.

Some Observations on the Rôle of Certain Anaerobes in the Intestinal Flora of Infants.—Dr. LANGLEY PORTER of San Francisco presented this communication, which he said related entirely to that group of intestinal toxemias in which the abnormal stool bacteria were resistant to dietetic measures usually adequate to produce a change of flora. Very rarely in the course of this study certain specialized forms of colon bacilli had been encountered. These were highly facultative and extremely acid resistant. Thus far no effective

method had been devised for overcoming their interference when they were present in the stool. Investigation of the evacuations of the majority of patients whose stools showed a similar resistance to change in the floral balance revealed the presence of an unusual number of spore-bearing organisms, most often anaerobes, usually *B. welchii*, which interfered by virtue of their facultative powers. This facultative function enabled them to utilize any pabulum present. Because of their power in the active stage to use carbohydrate they were especially apt to interfere when any attempt was made to shift a proteolytic flora by feeding a high sugar diet. A diet limited in proteins and rich in carbohydrates would be effective in overcoming these facultative anaerobes and causing the disappearance of these spore-bearing anaerobes from the stools.

Some Experiments to Determine the Persistence of Extraneous Bacteria in the Gastrointestinal Tract of Guinea Pigs as Influenced by Diet.—Dr. A. GRAEME MITCHELL of Philadelphia presented this paper, in which he described the attempt at implantation of the *Bacillus pyocyaneus* in the digestive tract of the guinea-pig. He said that thus far the proof of the implantation of organisms in the intestinal tract rested upon very incomplete evidence. The *B. pyocyaneus* had several advantageous characteristics, which made it suitable for a study of this kind. The guinea-pigs were fed various diets containing the *B. pyocyaneus* for a period of three days, and were then killed at variable lengths of time afterward. Cultures were made from the heart blood, the stomach, the duodenum, the ileum, the cecum, and the colon. It was found that when guinea-pigs were fed on a diet of oats, hay, bread, and green stuff, *B. pyocyaneus* when fed disappeared from the gastrointestinal tract in three days. When oatmeal was given as a sole article of diet the *B. pyocyaneus* was found at seven and nine days after the last administration. The addition to the oatmeal of a small amount of green stuff or a certain amount of butter had apparently prolonged the period of persistence of the bacterium. On these slightly amplified diets pyocyaneus had been found to persist about two weeks with considerable regularity. There were reasons for believing that this persistence was probably apparent only. The animals on a strict oatmeal diet did not live long enough to enable a complete experiment to be carried beyond eight or ten days. Judged by the amount of green color produced in the culture the number of surviving organisms became progressively less the longer the interval following the cessation of their administration. On the basis of these experiments it seemed quite probable, the speaker said, that there was an effect of dietary deficiency which consisted in the depression of a normal mechanism controlling the implantation of extraneous bacteria in the gastrointestinal tract.

A Brief Report on Lactic Acid Milk.—Dr. DEWITT H. SHERMAN of Buffalo presented this report, based on original work performed by his associate, Dr. Harry R. Lohnes, and himself. Lactic acid milk, he said, was a therapeutic food of many years' standing, the beneficial effects of which were explained in various ways. At first the good results were supposed to be due to the Bulgarian bacillus. This idea had been stated to be incorrect. A second explanation offered was that the increased acidity of the gastric contents, as it passed into the duodenum, stimulated the intestinal secretions. This had been put aside. The third reason, which at present seemed most rational, was that lactic acid was efficient through Meltzer's law of "contrary innervation"; and it was productive of good results through the increased amplifications of the peristaltic wave, and by this increased motility function was increased. In the infant Meltzer's law was especially applicable because lactic acid milk seemed to act best in those cases that were undertone, with weakened or dilated gastric musculature. Dr. Sherman compared the relative value of protein milk with lactic acid milk and showed some of their differences. He questioned the extolled value of protein milk because its soluble salts were removed and its insoluble salts, those of calcium and magnesium, were in excess. He appreciated the value of protein milk in those infants whose tolerance for sugar was broken. Stress was laid on the acidity of the lactic acid milks as a reason for the infant refusing or rejecting it. The desired acidity was at 70 to 90 as measured by a decinormal sodium solution. To keep this acidity he gave two original methods for making lactic acid milk. The first was to culture the boiled, and hence sterile, milk, and put it away, at a temperature of 85° Fahr., in an ordinary child's icebox so commonly found in the household. It was to remain there over night and in the morning would be found of approximately the correct acidity. It was then boiled again to destroy the activity of the Bulgarian bacillus, and put away on the ice. The second method was even simpler. The boiled milk was cultured and allowed to stand in a warm place, and in twenty-four hours the acidity would reach 180 to 190, possibly 200, and acid reaction of sufficient degree to destroy the Bulgarian bacillus. This very acid lactic acid milk was then diluted with an equal amount of sweet milk and the correct acidity was secured. Upon adding the sweet milk a fine clotting occurred and, when boiling a second time, active stirring with a Dover egg beater was essential in order to obtain a homogeneous mixture. In order to make the formula flexible in reference to fat, Dr. Sherman said, a skimmed lactic acid milk was first used, and, as indications permitted, whole lactic acid milk was gradually substituted for it.

The Urgent Need of Dietetic Reform and the Duty of the Medical Profession Toward All the Young of the Nation.—Dr. W. E. SAUNDERS of St. Louis read this paper, in which he asserted that there was alarming degeneracy in the rural and urban population. Apparently brown bread and bean-eating Harvard recruits were the only exception. One-third of the youth of the nation had been found unfit for military service. Immigrants from the Ghettos of Europe, in spite of better wages and more abundant food, were rapidly degenerating in America. Negroes of the South were physically unfit because of a diet of commercial corn meal. Italians were failing because of a diet of macaroni made of white flour. White rice was utterly unfit for food. The first measure to combat H. C. L. was to stop the denaturing of all foods by Federal law. The Government investigation of 1907 was farcical. Existing pure food laws were aimed against sophistication only. When these laws were passed no one knew the deprivation of the essential elements contained in staple foods was more deadly than sophistication or substitution; nor did any one suspect that a diet of maintenance for the adult might fail to sustain growth in the young. The teeth of the children were in far worse condition than that of their parents, according to the verdict of the dentist. The young suffered most from the fundamental dietetic errors of the nation. Imperfect and early diseased teeth, fragile bones, weak muscles, exhausted nervous system, recurrent infections, visceroptosis, stunted growth, inordinate appetite for sweets and meat, craving for stimulants and for excitement, and inability for sustained effort might be traced to dietetic errors. Tendency to acidosis from a diet of pure sweets and of denatured cereal foods, almost destitute of the necessary mineral constituents, and vomiting of pregnancy were greatly aggravated by the same vicious diet. The common saying was that a woman must lose some teeth after every pregnancy need not prove true if only natural foods were used. Fractures sometimes remained ununited for months until the proper diet was instituted. Various causes had been assigned for the failure of the modern woman to suckle her child, but the most potent was, without doubt, the use of denatured cereal foods. Perhaps imperfect development of the endocrine glands, almost certainly a predisposition to cancer—all this train of evils that afflict the young and the future worker could be laid to the insane diet of the American people of the present day. The young of the nation had hardly as yet tasted the benefits of the newer knowledge of nutrition except those fortunate individuals who might chance to be under the care of a pediatrician. The remedy for this deplorable condition was two-fold: (*a*) diffusion of knowledge, (*b*) Federal and State legislation initiated by the American Pediatric Society and all other medical societies.

(*To be concluded.*)

State Medical Licensing Boards.

STATE BOAD EXAMINATION QUESTIONS.

FLORIDA STATE BOARD OF MEDICAL EXAMINERS.

Jacksonville, June 14, 1920.

(*Continued from page* 294.)

OBSTETRICS.

1. (*a*) What is the umbilical cord, and how formed? (*b*) Describe the placenta.
2. Give signs of pregnancy and their relative value.
3. State the significance of the albuminuria of pregnancy, and give an outline of its treatment.
4. Give cause, diagnosis, and treatment of uterine inertia.
5. Give technique of intrauterine irrigation and state when its employment is justifiable.
6. What is placenta prævia? Name its causes, varieties, symptoms, dangers, and management.
7. Give etiology, prognosis, and symptoms of puerperal fever.
8. Describe the proper measures for the care of the new-born child.
9. What diseases of the mother are apt to interfere with the fetus in utero?
10. Define and give the treatment and prophylaxis of ophthalmia neonatorum.

GYNÆCOLOGY.

1. Give the gross anatomy of uterus and ovaries.
2. Describe the course of the ureters in the pelvis.
3. Should you normally feel a hard body in any of the four fornices of the vagina? If so, which one, and what is it?
4. Mention the principal new growths occurring on the vulva.
5. What are the frequent complications and results of gonorrheal vaginitis?
6. How would you differentiate pelvic haematocele from impacted feces?
7. Describe the factors which influence the onset of menstruation. What is the average frequency and duration of each period?
8. How would you differentiate an anteflexed uterus from a fibroid tumor in the anterior wall?
9. Give the technique for repair of lacerated perineum.
10. Give the symptoms and treatment of carcinoma of uterus.

ANSWERS.

OBSTETRICS.

1. The *umbilical cord.*—"At term the cord has been compared to a 'twisted rope of tissues,' extending from the placenta to the child. The cord is of a glistening grayish-white color, of varying thickness, and is usually about 22 inches long, but may be either much longer or shorter. In structure the cord consists of a covering of epithelium continuous with that of the amnion, which surrounds a jelly-like matrix called Wharton's jelly. This consists of mucin, branched corpuscles, and embryonic connective-tissue cells. Within this substance the two arteries and one vein run in a spiral course, usually from left to right; it is to the fact that the growth in length of the vessels exceeds that of the rest of the cord that the twisted appearance of the latter is probably due."—(Jewett's *Practice of Obstetrics.*)

At full term the *placenta* is a soft, spongy mass, roughly saucer-shaped, from six to nine inches in diameter, about three-quarters of an inch in thickness at the central point, and weighs about one pound. It is *formed*, partly from the mucous membrane of the uterus, and partly from the chorionic villi. Its *functions* are: (1) To supply nourishment to the fetus; (2) to act as a respiratory organ for the fetus; (3) to act as an excretory organ for the fetus; (4) it is also supposed to provide an internal secretion. Its *usual location* is on the anterior or posterior wall of the uterus, near the fundus.

2. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle. *Doubtful signs of pregnancy:* (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness. *Subjective signs of pregnancy*, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements. *Objective signs of pregnancy*, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina; pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

3. *Albuminuria of pregnancy:*—"This is the most common manifestation of the toxemia of pregnancy, occurring once in every twenty to thirty patients. It is more frequent in primigravid women, and usually first shows itself about the fifth month, though sometimes earlier. The term covers a very wide range of symptoms, from the mildest right up to the most severe, just short of the convulsions and coma that characterise eclampsia itself. To cases only exhibiting the mildest symptoms, slight albuminuria, lassitude, slight headache, and perhaps a little swelling of the ankles, the term 'the kidney of pregnancy' has been given. Rest, laxatives, and a less nitrogenous diet will put matters right, and the importance of the condition lies merely in the fact that it is the earliest sign that the kidneys are suffering from the strain put upon them, and are liable to give way further if not watched, and, if need be, relieved.

"Apart from these very mild cases pre-eclamptic toxæmia may show itself in symptoms of varying severity—general malaise, headache, either frontal or occipital, lassitude or irritability, disturbance of vision varying from slight dimness to complete blindness, edema of ankles, lower limbs and vulva, and possibly of other parts as well, somnolence, dizziness, sickness, and severe pain in the epigastrium. . . . The condition of the urine in pre-eclamptic toxemia is of the greatest importance. In the slighter cases the quantity is not greatly affected, but it contains albumen, and hyaline and granular casts. In more marked cases the quantity is always diminished, and it contains a considerable quantity of albumen, casts, and some blood corpuscles. The total quantity of nitrogen is diminished; the proportion of urea is lowered, while the ammonia, and undetermined or 'rest' nitrogen is proportionately increased. A marked drop in the urea output, along with a large amount of albumen, indicates a severe case liable to go on to eclampsia, if not treated at once. . . . Another feature of great significance is the arterial pressure. It is usually raised, and in severe cases it becomes markedly high—a point of importance in making a prognosis."

Treatment.—"The urine should be examined every month in the first six months of every pregnancy, no matter how normal it may seem, and every fortnight in the last three months. If albumin is present, the amount should be estimated in an Esbach tube, and the urea in a Doremus ureometer. The total quantity of urine per diem should also be ascertained. The principles of treatment are to relieve the kidneys by free elimination by the bowels and skin, and by diminishing the nitrogenous part of the dietary; and at the same time to prevent any further interference with the renal functions by guarding against cold. In mild cases where the albuminuria is the sole symptom, the patient should be warned to rest and guard against cold. The diet should be restricted to milk food, with bread and butter, and a little fish or chicken once a day, and the bowels should be made to act freely once every day."—(Johnstone's *Textbook of Midwifery.*)

4. *Ulterine inertia* may be *caused* by: Debilitated constitution, exhausting disease; uterus weakened because of congenital malformation, inflammation, or too frequent child-bearing; adhesions to neighboring struc-

tures; tumors of the uterus or neighboring tissues; distention of the bladder or intestine; displacement of the uterus; premature escape of the liquor amnii; pregnancy in an old primipara; hydramnios; twin pregnancy; fright or mental emotion.

The cervix dilates slowly or not at all; if the membranes are ruptured the fetus makes little or no advance; the woman shows evidence of fatigue and may be anxious or restless; the skin gets dry, the pulse small and rapid, the temperature elevated, the tongue dry and furred, nausea and vomiting may supervene, and delirium and coma may follow.—(From Webster's *Obstetrics.*)

Treatment consists in removing the cause if possible; the bladder and bowel should be emptied; opium, morphine and chloral may be given so that the patient may get a little sleep, at the same time food may be administered; the uterus may be massaged through the abdominal walls; hot vaginal douches are sometimes helpful; the vagina may be distended with a rubber bag; if the membranes are ruptured, a Champetier de Ribes bag may be placed in the lower part of the uterus; an anesthetic may be necessary; quinine, strychnine, and ergot have been recommended by some, and condemned by others; the newest remedy is pituitrin, which may be injected into the muscles in doses of from 1 to 1½ c.c., provided that the cervix is dilated and that there is no obstruction to delivery.

5. *Intrauterine irrigation is indicated* when there is any indication of infection during labor or in the puerperium, also after post-partum hemorrhage.

"The best composition for an intrauterine douche is one of the following: (1) Tincture of iodine 4 drams, alcohol (ethyl 95 per cent., *never* methyl or wood alcohol) 8 ounces, sterile water up to four pints; or (2) formalin (40 per cent.) 30 drops, glycerin 2 ounces, water 1 pint; or (3) lysol solution 1 dram to 2 pints. The temperature of the douche should be 110° to 115° F. The patient is placed in the dorsal position, cleansed, the cervix exposed through a bivalve speculum, the intrauterine catheter (best the *large* Bozemann) inserted by sight, and the solution allowed to flow by gravity, with not more than two feet head. The douche bag or can and catheter are boiled and the solutions made up with sterile water."—(Hirst's *Manual of Obstetrics.*) Particular attention must be paid to asepsis.

6. *Placenta Prævia* is the condition in which the placenta is attached in the lower uterine segment and may be near or over (partially or completely) the internal os. The *causes* are unknown; multiparity, frequent pregnancies with subinvolution, and abnormalities of uterus, placenta or cord are said to predispose to this condition. *Varieties:* (1) *Central,* when the placenta completely covers the os. (2) *Partial,* when the placenta overlaps the os. (3) *Marginal or lateral,* when the placenta reaches the margin of the os but does not overlap it. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Dangers:* Hemorrhage, sepsis, death of the mother, death of the fetus.

Treatment before term: Rest in bed, with or without a *tampon,* will arrest hemorrhage for the time; the sinuses are closed by thrombi, and the case may go on to term or another hemorrhage. The patient should be allowed cold drinks; opium may be used where pain is present. If the hemorrhage is great, it is safer to induce labor at once than to wait. Occasionally no hemorrhage occurs during pregnancy, not even in labor.

Treatment at term: (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation, turn the child and make the breech engage in the os; or, if the head presents, the forceps may be used, if speedy delivery is necessary. Stop the hemorrhage by a tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix. version and immediate extraction of the child.

7. *The bacteria which causes puerperal fever* are: Streptococcus pyogenes, staphyloccoccus pyogenes aureus, gonoccoccus, bacillus coli communis, bacillus diphtheriæ, bacillus typhosus. They are generally introduced by the fingers of the physician or nurse, or by instruments, or general lack of cleanliness. The results are shown by chill; rapid rise in temperature, to about 103° or 104°, higher in the evening than in the morning; sweats; rapid pulse; depression; dry tongue; anorexia; carphologia; scanty, high-colored, albuminous urine; restlessness; sometimes delirium or coma. The uterus is large and tender; the lochia are diminished or suppressed; the milk secretion is often suppressed; pain in the abdomen; peritonitis may develop. The prognosis is grave, and depends on the promptness and thoroughness with which the septic condition can be removed.

8. *Care of infant:* After the cord has been ligated and cut, the eyes should be cleansed with a saturated solution of boric acid, after which, if there is any vaginal discharge from the mother, 1 or 2 drops of a 1 per cent. solution of silver nitrate should be instilled in each eye. The mouth should also be gently cleansed, for which may be used a soft cloth and boiled water. The vernix caseosa should be removed by means of some oily substance. The baby should be bathed in water at 100° F., carefully dried, and the cord dusted with some antiseptic powder. Sponging should be practised for 10 days, after which a full tub-bath at 98° F. should be given daily for 6 months. The temperature may then be reduced to 95° F., and at the end of a year to 90° F. The binder and clothing should be woolen. If the infant's extremities are blue or cold, external heat should be applied. The diapers should be made of flannel, and dusting powders should be used to prevent chafing."—(*Pocket Cyclopedia.*)

9. *Diseases of the mother which are apt to interfere with the fetus in utero.*—Nephritis, syphilis, diabetes, tuberculosis, toxemia, anemia, endometritis, metritis, lead and other poisons, smallpox and other infections.

10. *Ophthalmia neonatorum* is an infectious, purulent inflammation of the conjunctiva in the new-born. It is due to the gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc. *Prophylaxis.* Immediately after birth the eyelids of the new-born child should be washed with clean warm water and onto the cornea of each eye should be dropped one or two drops of a 1 or 2 per cent. solution of nitrate of silver. This procedure will prevent ophthalmia neonatorum in doubtful cases; it will do no harm in innocent cases; and it is the first stage in treatment if gonorrheal infection is present. *Treatment.*—Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

GYNECOLOGY.

1. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity, and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments. (1) *Broad ligaments,* which extend outward on each side from the side of the uterus to the side of pelvis. (2) *Rectouterine ligaments,* which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments,* which extend from the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) The *ovarian ligaments,* which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) The *uterosacral ligaments,* which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac synchondrosis.

The *ovaries* are two in number, and correspond to

the testes in the male; they are of a flattened ovoid form, vertically placed in the posterior part of the broad ligament. By its anterior border the ovary is connected to the broad ligament, and by its lower pole to the uterus by a proper ligament, extending to the superior angle of the uterus, and called the *ligament of the ovary*. The lateral surfaces and posterior borders are free. The superior pole and posterior border are embraced by the Fallopian tube; on its inner surface it is in relation with small intestine in Douglas' pouch, and externally lies in a peritoneal fossa between the external and internal iliac vessels as they diverge. The vessels enter the hilum at the attached anterior border.—(*Aids to Anatomy.*)

2. *Course of the ureters in the pelvis (in the female).*—The ureter runs from the sacro-iliac articulation down and backwards to near the floor of the lateral pelvic wall, whence it enters the broad ligament. This portion is 3 inches long, and lies first in front of, or to the inner side of, the internal iliac vessels; then forms the posterior boundary of the obturator fossa, and lies immediately behind the ovary. The second portion, 2 inches long, traverses the parametrium between the layers of the broad ligament, ½ inch above the lateral vaginal fornix, and separated from the supravaginal cervix by ¾ inch. Here it is closely enveloped in the venous plexuses, and is crossed above by the uterine artery. Thence it converges towards its neighbor of the other side, so that it is even nearer the cervix in front than laterally (and may be detected by palpation from the vagina), to enter the bladder at the basal angle of the trigone 1 inch below the level of the external os, and just above the roof of the vagina, its course through the bladder wall being very oblique, and measuring ¾ inch in length."—Macewen's *Surgical Anatomy.*)

3. If the uterus is anteflexed, the fundus may be felt in the anterior fornices; if the uterus is retroflexed the fundus may be felt in the posterior fornices.

4. *New growths occurring on the vulva* are:—Lipoma, fibroma, angioma, papilloma, sarcoma, carcinoma, and cysts.

5. *Complications and results of gonorrheal vaginitis* include:—Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands. It often leads to chronic invalidism, and may be the cause of death.

6. *Pelvic hematocele* is an accumulation of blood in the pelvis, due to rupture of a blood-vessel; it is generally due to rupture of a tubal pregnancy, or to a tubal abortion, or disease of the ovary, or perimetritis. *Symptoms:* Pain, which is sudden and severe, over abdomen and pelvis; nausea, cold perspiration, cold extremities, pulse rapid and weak, pinched features, and shock. It is most likely to be mistaken for an ectopic gestation; but in the latter there will have been the subjective symptoms of pregnancy.

In *fecal impaction*, there will be none of the above symptoms, with the possible exception of pain.

7. *Factors which influence the onset of menstruation.*—"Circumstances modify the age at which the first menstruation takes place; thus, the menses appear earlier *in hot climates*, but the difference between the hottest and coldest climates is only about three years; the influence of *race*, which remains potent in spite of climatic changes; *occupation and mode of life;* luxury, stimulants, indolence, hot rooms, pruriency of thought, etc., render the woman precocious, while opposite conditions retard the menses; general robustness of constitution and vigorous health promote the development of menstruation, and it is delayed by feebleness and debility. On the other hand, a very tall woman with large bones and muscles will require more time to complete her growth, and hence the reproductive functions will be belated."—(King's *Manual of Obstetrics.*)

Menstruation lasts from five to six days, and the average amount of blood is about five ounces. It begins at puberty and occurs periodically at about 28 days interval, until the menopause; it is absent during pregnancy and early lactation.

8. An anteflexed uterus may be differentiated from a fibroid tumor in the anterior wall by a conjoined examination and the uterine sound.

9. *Operation for recent laceration of the perineum.*—"The parts are cleansed and a pledget of sterile cotton or gauze pushed up the vagina to stop any flow from the uterus obscuring the wound. The sutures (preferably of aseptic silk) are passed with a moderately curved needle about 2 inches long as follows: Beginning at the posterior end of the laceration (that nearer the anus), the needle enters the skin near the edge of the wound and follows a circular course until its point appears at the very bottom of the laceration (a finger of the other hand in the rectum guarding against its penetrating that canal); it then enters the opposite side of the laceration at the bottom of the wound and comes out of the skin opposite its point of entrance, having followed a similar circular course to that pursued on the other side where it first went in. The ends are *loosely* tied or secured by catch-forceps, until the requisite number of sutures are passed in a similar manner (half an inch apart), when the wound is again cleansed, the vaginal plug removed, and the sutures tied tightly enough to coapt the parts without injurious constriction, the order of succession in tying being that in which the sutures were passed.

"In 'complete' lacerations—those of the third degree—through the sphincter ani to the rectum, the operation is more difficult. The rectal tear is first stitched with *catgut* sutures (a short, curved needle being used) and going through the rectal wall only. The sutures are tied on the inside, so that the knots are on the mucous membrane of the bowel. They begin from above and come down to the sphincter ani, the cut ends of which are drawn out with a tenaculum while the sutures penetrate them. These *catgut* sutures need not be removed; they will digest in the tissues and disappear of themselves. The posterior wall of the vagina is next sutured with fine silk, from above downward toward the hymen. Finally, skin sutures through the perineum itself, including muscles of the pelvic floor (as just described for lacerations of the first and second degrees) complete the operation. The silk sutures may be removed in about a week. Antiseptic dressings are applied as after an ordinary labor, extra care being taken to keep the wound aseptically clean by daily irrigation with the creolin solution."—(King's *Obstetrics.*)

Operation for old laceration of the perineum.—"Lateral tears are best repaired by the Emmett operation. With the patient in the lithotomy position, guide sutures or tenacula are passed through the apex of the rectocele and through each labium majus at the lowest carunculæ myrtiformes. By drawing on the lateral suture and pulling the central suture downward and to the opposite side, the lateral sulcus appears as a triangle with the apex up in the vagina. This triangle is denuded of mucous membrane by cutting off long strips by means of forceps and scissors, or by dissecting the mucous membrane off in one piece. The triangle on the opposite side is treated in the same manner, and the denudation completed by removing the mucous membrane between the bases of the triangles and below the central suture. Each lateral triangle is closed by interrupted sutures of chromicized catgut or silkworm gut, the latter being shotted. The needle, which should be curved, is entered near the margin of the wound on the outer side. passed deeply to catch the fibers of the levator ani, and brought out at the bottom of the sulcus, at a point nearer the operator; it is then reinserted at the bottom of the sulcus, and passed upward and backward in the rectocele, to emerge opposite the point of the original insertion. The opposite triangle is treated in the same manner, which leaves a small raw area externally to be closed. The upper or 'crown stitch' passes through the skin of the perineum below the lateral guide suture. then through the rectocele below the central guide suture, and finally through the tissues below the opposite guide stitch. As many sutures as may be necessary are inserted below this. If silkworm gut is used, the stitches should be removed on the tenth day. The external genitals are irrigated with weak bichloride of mercury solution after each urination; catheterization should, if possible, be avoided. The bowels are moved on the second day. Internal douches are not needed unless there be infection. The patient should be kept in bed two weeks, and heavy work and sexual intercourse forbidden for three months."—(Stewart's *Surgery.*)

10. *Carcinoma of the uterus is diagnosed* by the his-

tory, symptoms, physical signs, and microscopic examination. It is a disease of advancing years, and generally occurs after the menopause; nulliparæ and multiparæ are equally liable. The chief symptoms are hemorrhage and discharge with an offensive odor, pain, and cachexia. The cervix is soft, the uterus enlarged, and tender. The uterus must be curetted, and the scrapings examined by the microscope.—*Treatment* consists in thorough removal at the earliest possible moment. This is often impracticable, because of the delay in seeking advice.

Therapeutic Hints.

Mild Diabetes Mellitus.—Woodyatt, in a brief discussion of mild cases of diabetes mellitus, says when the patient comes in it is a good plan to give him a talk somewhat as follows: "Your body is a gasoline motor. The gasoline is represented by the sugar. It contains power, and when burned gives energy. You have in your body a certain organ which plays the part of the spark plug, viz., the pancreas. It provides something which is necessary for the ignition of sugar. When sugar appears in the urine, it is like black smoke from the exhaust of an automobile. The motor is flooded. Good fuel is going to waste." It is important to have the patient understand the rationality of what one is trying to do for him, inasmuch as he will have to carry out the treatment at home. The first object of the treatment is to put the pancreas at rest. When the body is flooded with sugar it may be assumed that the sugar constantly stimulates the pancreas until it is driven into a state of fatigue so that it does not "spark" as it should. After a rest the pancreas may show a marked degree of recovery. The tolerance improves. To put it at rest the excess of sugar must be got out of the blood. The patient must be desugarized, and he must be told why and how this is to be accomplished. To an ordinary mild diabetic Woodyatt commonly gives a diet consisting of 400 gm. of vegetables containing not over 5 per cent. of carbohydrate; that is, lettuce, tomatoes, cucumbers, string beans, cauliflower, etc. In addition to the 400 gm. of greens, the patient may take water, clear soups, tea or coffee, salt and pepper, as desired, since these things have no food value worth considering in this connection. A salad dressing composed of mineral oil as described by Joslin adds to the patient's comfort, and the bran-agar muffins introduced by Allen may also be used if desired. On the first day of the diet the patient should keep warm and quiet, in order not to expend too much energy while he is not receiving any from his diet. This low diet contains only 12 gm. of carbohydrate and some 4 gm. of protein. He must stay on this diet until he becomes sugar-free (mild case), at which time he is through with it. In order that he may know when he is sugar-free the patient must be taught, unless there is some psychological reason for doing otherwise, how to make a sugar test. When he is sugar-free he is kept on this diet at least one day, to make sure, and then he is started on the second objective. Let the pancreas rest for ten days. During that time, however, since there has been protein starvation, give the preference to additions of protein. A practical rule is to build up the protein until there is 1 gm. of protein for every kilogram of body weight, with only such fat as can not be separated conveniently from the eggs and meat given. If at the end of a week, in a mild case of diabetes weighing 60 kg. one has succeeded in introducing 18 gm. of starch and in adding 60 gm. of protein and 40 gm. of fat, one is in position to begin to build up the calories, which is the third objective. Frequently at this stage Woodyatt prefers to put in first more carbohydrate, then more protein, then more fat. The total caloric allowance should be on a basis commensurate with the individual's physical activity. Having the patient in a protein equilibrium, caloric equilibrium, and still consistently sugar-free, the fourth objective is to ascertain his tolerance. For that purpose Woodyatt usually relies on straight white bread, because its composition is fairly uniform. Of that he administers 25 gm. additional every day or every other day until he finds an amount which is just sufficient to produce a recurrence of glycosuria. Having obtained that, he is again desugarized, making a total subtraction of the bread so as not to delay desugarization. The patient is then systematically taught how to vary his diet at home and still maintain the same balance. Patients do well and refrain from breaking their dietaries when they know what they are trying to accomplish and have been thoroughly taught how to carry out their own treatment in their own homes with the implements and materials and under the conditions that they find there.—*Journal of the Missouri State Medical Association.*

Lupus Erythematosus.—Small has found the following method applicable to nearly every case of lupus erythematosus. It has been used for years at the Edinburgh Dispensary for Diseases of the Skin. After gently washing the part with ether and allowing it to dry, it is vigorously rubbed with a mixture of ac. carbolic. liq. 1 part, ac. lactic fort. 4 parts, by means of a glass rod. It is necessary to use only a few drops at the time. The rubbing is continued until the part is practically dry, which usually requires two or three minutes. If there is no discomfort the patient is to leave the part alone; if slight irritation develops, he is directed to apply vaseline constantly. A slight inflammatory reaction follows this treatment immediately, and in a few days desquammation takes place, leaving the area pinkish and relatively healthy. When exfoliation is complete the application is renewed, not oftener than once a week. The appearances and chronicity or acuteness of the disease govern the frequency of application. Too frequent application may give rise to ulceration, with unfortunate results. Improvement follows one or two treatments, and if these are persisted in the ultimate result is quite satisfactory.—*British Journal of Dermatology.*

Subcutaneous Injections of Camphor in Influenza.—A. D. Gorman reports that in a certain large stationary hospital in France during the severe influenza epidemics, he gave, almost as routine, intramuscular injections into the gluteal region of camphor in oil, gr. v. in *m* xv, every four hours, without untoward results in a single instance.—*British Medical Journal.*

MOBILIZATIONS IN INJURED, INFECTED, AND FRACTURED JOINTS.

BY CLARENCE A. McWILLIAMS, M.D., F.A.C.S.

NEW YORK.

THE most valuable acquisition that the surgery of the war has given us is the Willems method of treating joint lesions, whether aseptic or infected, by immediate, active, and continuous mobilizations. To accept this method in civil practice, as it must be, will mean the complete revolution of the old, firmly established dogma of the necessity of immobilization in all joint injuries. This change can be effected only by the demonstrated superiority of this method over others in the successful treatment of the vast number of severe injuries of joints which occurred during the war. Willems gives the figures in regard to the final outcome of his treatment in 100 consecutive knee cases, eighteen of which were accompanied by a purulent synovitis of a virulent type, chiefly streptococcic. Among these 100 patients there were no deaths and no amputations. There was one resection, and there were two stiff joints. These are very striking and remarkable figures. In comparison, the results obtained in one evacuation hospital of the American Expeditionary Forces (which I know of) suffer markedly, due to the too early evacuation of patients, which necessarily resulted in immobilization, and the half-hearted attempts at mobilization. Of eighty-two patients with knee injuries, sixteen became infected, nine died, three had amputations, seven suffered complete ankylosis, while in one case resection was performed. The Willems method must become the rule in civil practice if we are to reap its benefits, and if we are to decrease the "bone setter's" clientele. The material on which the "bone setter" thrives should never exist. The formation of more than temporary adhesions in acute joints should be practically eliminated by the regular practitioner. The two great friends of the "bone setter" are fixation by splints and rest, while his greatest enemy is the treatment of recent injuries by mobilizations.

Pathology.—Let us examine the changes which take place in a joint, such as a knee, which has been immobilized for some time (Mennell[1], Alexander[2]). Adaptive shortening of the quadriceps takes place due to the wasting of its muscle fibers. An elastic, connective tissue sheath surrounds each muscle fiber and each group of fibers. The sheath loses its capacity of elasticity when its function of shortening and lengthening is in abeyance for any length of time. Restoration of function alone restores this lost elasticity. In addition, there is considerable shortening of individual muscle fibers which become partially degenerated. Cells in this state tend to be replaced by fibrous tissue which further shortens them. The individual fibers are surrounded by lymph spaces which drain into lymph capillaries and this lymph is coagulable because it contains fibrinogen and thrombin. Coagulation will, in consequence, result from those influences which cause clotting of the blood, such as trauma, septic foci and stasis. The fibers become glued together by these coagula, and intramuscular adhesions are formed. A certain degree of regeneration goes on, but these young muscle cells will survive only if function is maintained. If not, their failure to live will only increase the amount of fibrous tissue formed. Therefore the quadriceps, for example, after prolonged immobilization is a muscle which has become shortened, has practically lost its contractility and extensibility, and is pervaded throughout with fibrous tissue, gluing the fibers together, and, to a large extent, actually replacing the muscle cells. The lymph spaces are filled with coagula and detritus, due to stasis of the circulation. The ligaments, tendons and capsule about the joint suffer the same changes as the muscle, they lose their elasticity and become shortened. In addition, there may be the scars of healed sinuses reaching to the bone. This is a picture of a muscle which results from the atrophy of disuse. In the neighborhood of a fracture and about each sinus the muscle is glued fast to the bone by dense scar tissue. Consequently, after prolonged immobilization, there are periarticular, perimuscular, and intramuscular adhesions with contracted and imperfectly functioning muscle cells. To these may be added lesions within the joint leading to fibrous bands and to erosions of the cartilage, the results of trauma and sepsis. Most of these changes can be eliminated by proper mobilizing methods instituted at the earliest moment. Willems' mobilization treatment, it must be remembered, is applicable to *acute* conditions only, at their very inception. It is intended to prevent the shortening and inelasticity of the muscle fibers and sheath, to forestall the formation of fibrous tissue, to prevent the coagulation of the lymph through stasis, to maintain the nutrition, and, in the septic cases, to facilitate drainage. Because it is impossible to carry it out alone, Willems' treatment is of no value when there are firm adhesions in the joint, when shortening has taken place in the muscle and periarticular tissues, and when atrophy of the muscle has occurred. It is then too late to apply Willems' method, and other measures must be instituted. Some have condemned his method because they have applied it in the

chronic cases and have not obtained the results with it that they expected.

I shall divide the subject into the mobilizing treatment (1) of the acute cases (*a*) aseptic, (*b*) infected, and (2) of the chronic cases.

The Acute Cases.—In general the Willems treatment is the same, except for the preliminary procedures, whether a joint lesion is infected or aseptic. In the case of recent injury, one should excise the contused and infected soft parts, extract foreign substances, remove the rough and dirty edges of the bony wounds, extract detached bone fragments, wash out the cavity, and completely close the synovial membrane. In an infected joint one must perform an arthrotomy by appropriate incisions and leave the wounds open without any tubes or drains into the joint, and no splints are to be applied. Following these preliminary procedures, the technique in the two types of acute cases is the same. To obtain results one must absolutely follow the methods which Willems has so carefully and successfully worked out in a large number of cases.

Technique.—As soon as the patient has recovered from the effects of the anesthetic, he is made to move *actively* the affected joint as much as he will. No passive motions are ever employed in any stage of the treatment in the acute cases. The patient will only move the joint *actively* to the extent that no great amount of pain is thereby caused, hence no additional trauma will be produced. In the case of the knee, the hands of the patient grasp the thigh, and lift it from the bed, thus flexing the leg on the thigh. A useful, supplementary method is to place a small pillow under the thigh and to allow the leg to hang from this, very shortly gravity will overcome resistance to motion. Thereafter the patient is made to move the joint *actively every two hours*, day and night. The first two or three days are the most important time in which to carry on these movements, since they are then made before inflammatory reaction has taken place. Stasis with its coagulation of lymph has not occurred, and consequently the movements are almost painless. At first the range of movements is slight, largely from fear of pain, but as this is felt to be groundless, the range of motions is rapidly increased by the patient himself. The more nearly continuous the movements are made, without muscular exhaustion, the better for the patient. It cannot be too strongly insisted that the movements must be begun just as soon as possible after the effects of the anesthetic have worn off, for when stiffness has once set in, then the difficulty of mobilizing the joint is much increased and the pain is much greater, due to the inflammation set up around the ruptured and traumatized new fibrous tissue.

In an aseptic joint lesion, a complication will very frequently set in on the second or third day, which demands a thorough revision of the previous method of treatment. It is the collection of serum in a joint. This used to be treated by splints and immobilization; but this method is now obsolete, as it should be in any case of acute or chronic synovitis (hydrops) of a joint. The mechanical influence of the fluid alone, and not inflammation, causes the abolition of any possibility of motion of the joint. The fluid should be at once removed by aspiration, when motions will be found to have returned as before. The active mobilizations should immediately be continued as though there had been no collection of fluid in the joint. Aspiration may be required a number of times. Bacteriologic examination of the fluid will detect the onset of infection. This method of treating "acute or chronic water" in the knee, from any cause, is beyond comparison, superior to our old immobilization treatment in its results; and it shortens immeasurably the duration of the effusion. On the second or third day, following an operation on a joint, the patient should be made to walk without crutches. It will be noticed that nothing is said about massage. If active motions are carried out conscientiously from the start, there will be no absolute necessity for massage, though this is a very useful adjuvant. Electricity and baths have very little place in treating acute joint lesions. In infected joints, active motions are the best means of obtaining adequate drainage. With each muscular contraction the synovial surfaces are brought in contact and all the pus is thoroughly forced out of the joint. If adequate exit for it is provided, the pus may often be seen ejected through the incision openings in spurts coincident with the muscular contractions. No irrigations are to be used and no drains. The dressings are to be changed only when they are soaked. With such treatment from the start, the pus does not burrow along the soft parts, the cartilages remain uninfected, as do also the bones, and there is little absorption into the circulation of septic toxins because the drainage is efficient, hence the constitutional effects of the sepsis are almost nil. There is none of the profound exhaustion that we see in patients treated by the immobilization method. Amputations are most infrequent. There is no necessity for any complicated incisions, such as the U-shaped incision cutting the ligamentum patellae, because drainage through simple incisions is amply sufficient, provided active movements are frequent enough, early enough, and are thoroughly carried out. Pain is never severe enough to prevent active motions if the movements are begun *immediately* after the operation. Later patients soon learn that the surest way to overcome pain is by making the motions, since by this means the best evacuation of pus is accomplished. True pain is only present when the drainage is insufficient, whether the fluid is sterile (hydrops) or infected. In the case of hydrops, drainage is accomplished by aspirations, in suppurative arthritis through appropriate incisions aided by the compressive effects of the muscular contractions. A very great advantage of this treatment, in the septic cases, is the simplicity of the dressings. No drains and no irrigations are used, hence great comfort to the patient is thereby afforded.

If mobilizations have been demonstrated to be effective in the very severe joint injuries of war, surely that method of treatment will be even more effectual in the much less severe injuries of civil life. In comparison with joint war injuries, those seen in civil life are child's play.

There are but two contraindications to the mobilizing treatment, as outlined above. These are:

1. Primary destruction of the ligaments and of the articular capsule. Here there is too great mobility and muscular contractions will only produce

deformity or dislocations. When the destruction, however, is only partial, mobilizing methods may still be applied.

2. Intra-articular fractures in which the fragments will be displaced by the motions, thus causing a dislocation. One should be thoroughly convinced, however, that such displacement will be produced before depriving the patient of the great advantage of the active movements. It would be well to ascertain, under the fluoroscope, the effect of the active motions on the fragments before interdicting them. Without such control it is easy to assert that displacement will occur, as a consequence of the deep-rooted but usually groundless fear of mobilizations.

Summary.—The lessons learned in the war through the use of Willems' mobilizations must be carried over by the surgeons to the treatment of most of the acute lesions of joints in civil practice. Thus:

1. The best treatment of hydrarthrosis has been already outlined.

2. After the removal of semilunar cartilages, or joint mice, the active motions should be instituted at once, immediately after the effects of the anesthetic have worn off. There need be no fear of any deleterious influence on the incision if this is properly repaired after removal of the cartilage. A continuous catgut suture closes the synovial incision edges and the overlying tissues are brought together by interrupted silkworm gut sutures, which should not be removed for twelve days. I have used this technic in half a dozen patients, instituting the active motions at once without splinting. Half of my patients have had to be *aspirated.* One patient drained sterile fluid from the joint for a week through the incision which opened of itself. Careful sterile dressings prevented any infection of the joint and the active movements were gone through with as though the joint were not open. The good results were astonishing in all cases. From a two to four months' disability, as would be the case under the old immobilization treatment, the time was reduced to a month at most, when full motions were obtained.

3. The joint incisions, after foreign bodies have been extracted, should be completely closed, after thorough lavage of the cavity with physiologic sodium chlorid solution followed by pure ether. The edges of the bruised and infected wound of entrance should be first excised until healthy tissue is reached. No drainage of the joint should ever be used in operations for the extraction of foreign bodies performed immediately following the injury. Drainage simply invites infection. A closed joint will take care of infection much better than we had any idea of. The Willems' mobilizations as just outlined should be exercised immediately. Aspiration of hydrops into the joint will probably be required, possibly a number of times. Rising temperature and local inflammation will presage the onset of infection. Streptococcic infection will require immediate opening of the wound, but no drains should be inserted. Willems' mobilization from the start, and walking should be carefully carried out. After a few days, if the temperature does not subside, and there is great and continuous pain, the drainage is not sufficient and the original wound should be enlarged. If the infection is produced by less virulent organisms than streptococci, the joint may be aspirated by means of a trocar and cannula, every other day, and washed out. A fall in the temperature will indicate subsidence of the infection while its increase will require opening of the wound and drainage without tubes. The best drainage is accomplished through adequate incisions by means of active, faithful mobilizations combined with walking without crutches.

4. Septic joints arise as complications of pneumonia and various other acute infections, as well as trauma. Streptococcus infections also occur as a result of acute traumatisms, direct or indirect. Direct contusion is a frequent cause, while severe twisting of the knee is an indirect cause, an instance of which is a soldier's falling into a shell hole and giving the knee a bad twist. Cases occur in which there is no ascertainable trauma nor any demonstrable general infection.

Duval[7] says, "The defensive reaction of the synovial membrane to infection is much more efficacious than that of other tissues, seeming to possess a bactericidal power; for, when a penetrating joint wound is examined bacteriologically a few hours after the receipt, bacteria are found in the skin, muscles, aponeurosis, and torn synovial edges, but the synovial fluid and the blood remain sterile for from twenty-four to sixty hours before the septic arthritis begins. The cavity thus remains aseptic for a considerable period while the parasynovial wounds are contaminated. During this intermediate period operation should be performed without delay, excising the contaminated tissues, including the bone and synovial edges, and finishing by complete closure of the wound without drainage. With this treatment most wounds will remain aseptic." Should septic arthritis follow, the treatment by reopening the wound and active mobilizations, as already outlined, should immediately be instituted. In neglected cases additional incisions may be necessary. One of the most valuable incisions for draining the popliteal space has been worked out by Major Abbott.[3] It consists of about a 4-inch incision along the inner and posterior border at the upper end of the tibia. This is followed up through the space under the incision of the popliteus into the knee joint and drains one of the synovial spaces in the joint that is most dependent and most difficult of access. This incision may be extended upward over the back of the internal condyle. By keeping in close contact with the bone the entire popliteal space can be drained with much less risk to the vessels than through the posterior incision.

Major Everidge[4] has devised a counterpoised, simple suspension splint which allows easy bending of the knee for use in mobilizations of suppurative arthritis of knees.

6. Fractures of the olecranon and patella have been treated usually by prolonged immobilization. This has produced a long disability caused by subsequent stiffness in the joints. Willems has overcome this by his early mobilizations. He encircles the fragments by a buried suture of silk or silkworm gut and brings the edges of the tears in the lateral tissues together by sutures. No splints are applied subsequently. Active, gentle motions are soon begun, but walking, in the case of a fractured patella, is delayed for ten days.

In fractures, generally, we are happily getting away from the prolonged immobilization previously throught necessary. Dowden,[5] who was a surgeon in charge of a 300-bed hospital for three years during the war, goes so far as to assert that splints are not necessary in the treatment of any fractures of the scapula, clavicle, and humerus. After the first three or four days the extremity is suspended in a sling alone. He has been treating these fractures in this way for twelve years with astonishingly good, final results. The method deserves greater recognition in selected cases.

The old method of treating fractures, generally, was to immobilize the joints above and below the seat of fracture as long as splints were deemed necessary to hold the fracture point. This resulted in a long disability, due to stiffness in the joints, and prolonged discomfort, attendant on efforts to mobilize them. The new and far superior method of treating fractures is to endeavor to immobilize the fracture point, but to leave the joints above and below free so that motions can be maintained in them. In the lower extremity the hinged extension splint suspended in a Balkan frame allows this to be accomplished admirably. In the upper extremity suspension in slings from a frame with traction by weights to the required extent, and in the proper directions, gives far better results than any other form of treatment, and is more comfortable.

Chronic Joint Adhesions.—The "bone setters" offices are filled with patients with chronic joint adhesions. The "bone setters" flourish because of the treatment injured persons receive, not because the patients have suffered injuries. Properly taken care of from the start with appropriate active mobilizations, few injured joints will become more than temporarily stiff. Mennell[1] has written a very instructive article on "The Practice and Results of Forced Movements." I wish to quote freely from this monograph and to acknowledge my indebtedness to him. There are neglected cases, also there are other cases in which adhesions will develop, whatever we do, in the presence of sepsis. If these form, it is very necessary to know how subsequently to handle them successfully. We must learn this method by imitating the "bone setter" in his work, and become familiar with the rules for the administration of forced movements, usually under an anesthetic. As has been previously shown, adaptive shortening of the whole muscular mass, including the sheaths, tendons, and ligaments has taken place, abolishing elasticity. When adhesions are present with limit of motions, the range of movement is only that allowed by the adhesions, while beyond this limit elasticity is lost. Mennell says, "When the patient has been anesthetized and movement has been performed through sufficient amplitude to rupture the adhesions, all further attempts at movement will tend to place undue strain on the fibrous tissue which has suffered impairment of its extensible properties, owing to disuse. Forced movement through the full anatomical range may thus inflict severe injury on the fibrous tissue that has lost the elasticity which is essential for the natural performance of the movement." He attributes the failures in his early work to: (1) Lack of knowledge of what the natural movements of the joint are, and (2) to a tendency to do too much.

Rule in Forced Manipulation under Anesthesia (Mennell).—No further attempt at movement is to be made in any direction when once a definite adhesion has been felt to give way, because, if so performed, injury will be inflicted on the fibrous tissue which forms a large bulk of the muscles which oppose the movement. Movements in other directions should be continued. The rupture of a pathologic adhesion is practically painless, and the local reaction is mild, but if the motion is carried beyond the limit set by the adhesion there will occur a severe inflammatory reaction due to the stretched and torn fibrous tissue in the muscular masses. If the motion is not carried beyond that allowed by the ruptured adhesions there will be but little subsequent interference with function. With active and gentle passive motions afterward, the lost elasticity will be restored up to the limit allowed by the next adhesion. The criterion of success after the manipulation should be that the patient has increased function; loss of function indicates error in technic. After a week or two a second manipulation again under an anesthetic should be undertaken, when an adhesion higher up is felt to give way. The "bone setter" arranges, from the beginning, for a series of manipulations. His plan is sound and deserves imitation. "Festinate lente" should be the rule. The grip in making the manipulation should provide as short a leverage as possible. The aim is to rupture an offending adhesion and *no more*, and should be done by a single, sharp movement rather than by a slow, gradual tearing, and should be checked at once as soon as the rupture of a single adhesion has been accomplished. A great error in technic is to give a succession of ineffectual tugs on the offending bands. As soon as the effects of the anesthetic have worn off,[6] the patient actively performs the motions which have previously been limited. If the movement is accomplished with more freedom and with less pain, the forced manipulation may be regarded as successful. If motion is more limited, and if the pain lasts more than a few hours, the manipulation may be regarded as having been too strenuously carried out. No period of rest after the manipulation should be required on account of pain. If rest is necessary, the good result may be in doubt. Functional use of the limb will rapidly restore elasticity up to the limit allowed by other adhesions. These must be ruptured by successive manipulations under ether.

For the appropriate movements of individual joints, I would advise consulting the monograph of Mennell.

Robert Jones[6] says that certain symptoms, following manipulation and passive motions, indicating injurious strain, may thus be formulated:

1. If pain occurs after manipulation, and is of short duration, movements may be continued.
2. If pain persists for long periods after manipulation, *rest* is indicated.
3. If the increased range of movement is maintained after manipulation, further movements can be prescribed.
4. If in spite of movements, even in the absence of great pain, the range is continually diminishing, rest is indicated.
5. The duration of pain when tissues are relaxed,

rather than its intensity, should be our clinical guide.

6. In overcoming adhesions and in subsequent manipulations, the joint should be put through its movements only once.

7. Voluntary movements can be safely allowed and should be encouraged since they are not followed by obstructive reaction.

The writer wishes to acknowledge his indebtedness to the authors mentioned below in the reference list. He has taken the liberty of quoting freely from them and makes little claim to originality in the preparation of this article. It was thought well to bring to the attention of the profession the salient points necessary in the mobilizing treatment of injured joints, both acute and chronic.

DILATATION AND PLICATION OF THE CAPUT COLI.*

BY DOUGLAS H. STEWART, M.D., F.A.C.S.,

NEW YORK.

IN an examination and comparison of urines that should be made a preliminary to any preparation for operative procedures upon colonic faults, or in the time of a prefatory survey of the conditions in a given patient, it is surprising to discover that there may be no relationship whatever between the extent of dilatation of the caput coli, the degree of displacement of either kidney or colon, and the amount of renal damage. Colonic traction upon the renocolic ligament will dislodge the kidney from its shelf in time, and one fairly constant accompaniment of colonic misbehavior is a faint trace of albumin in the urine, which trace may or may not prove to be introductory to additional signs of simple kidney irritation changing to a pathological state.

Should the colon be firmly adherent to the abdominal or to the pelvic wall or to both, then the colon bacillus is apt to manifest itself in the urine with the accompaniment of indican, etc. But even so the first contemplation of any supposed cognation between colonic condition and urinary evidence was most confusing. Some patients possessing a small relaxed colon would pass a urine that upon examination would reveal a most alarming renal condition. Which disclosure demonstrated only too clearly that the work of the kidney was being performed under a very considerable stress. On the contrary, aberration and abnormal activity of the caput were pictured by actinogram, fluoroscope, and photograph; but were not necessarily accompanied by anything in addition to a faint trace of albumin in the urinary verdict. Thus many cases of colonic stasis were not attended by the presence of the colon bacillus in the urine, while a fixed and more or less inflamed colon had a collateral urine that displayed that germ in more or less profusion together with the usual manifestations of intestinal toxemia.

Nor was it any less confusing to receive two detailed laboratory reports. One stated that the urine was normal save for its infinitessimal amount of albumin. The other report amplified the general statement that examination of the feces revealed "a highly acid, highly toxic stool." Both reports were made of the same patient's condition, both were made at about the same period of time, and both arrived in the same mail, though from different sources.

The aforesaid incident very naturally reminded the present writer of an interesting period in his medical life when the leaders of the profession indulged in much heated controversy as to a possibility or impossibility of rectal feeding. Learned colleagues stated that it could not be accomplished; but others equally learned asserted that the thing was an accomplished fact. Opponents of the method laid much stress upon the anatomy and physiology of the colon, upon the absence of Villi, upon its unbroken lining of columnar epithelium, and upon its complete lack of any sort of absorbent. The whole matter was finally adjusted because evidence was forthcoming by which it was shown that retained alimentary enemata passed through the ileocecal valve and thus gained access to the absorbents of the small intestine. The result, of experimentation that interests us here, is the unanimous conclusion that there must be some abnormal change in the colonic epithelium if intestinal contents could possibly pass through it; for under ordinary conditions of health that epithelium would stand like a barrier against the invasion or absorption of any intestinal contents whatever. Furthermore, the only way that guardian shield could be evaded was by a retrogressive flow through the ileocecal valve.

So far the reasoning of former days appears confirmed in every colonic case that has been studied in this connection. If the caput coli was to blame for the appearance of intestinal products or germ life in the urine, then there was to be found an origin or entrance located by a damage to the colon, or there was an incompetent ileocecal valve, or there were both conditions. Such lesions of the colon or faults of valve are discernable through careful palpation when an abdomen is explored. In Webster's "Diagnostic Methods," page 589, may be found these words of corroboration: "So long as the intestinal epithelium is unimpaired the colon bacilli do not

*Second paper.

pass into the organs or into the serous cavities of the body."

In the case of those patients from whose urine intestinal products have disappeared after colonic plication, either damaged epithelium was covered inadvertently through the manipulations of the operator; or else matters were restored to the normal so nearly that the epithelial lining of the colon was enabled to assume again its barricade function through a process of self-repair.

However, the point to be emphasized is that the urine is no dependable guide to the presence or absence of necessity for urgency in plicating the colon. Even with the most abnormal colonic conditions the urine may reveal but a 1 per cent. output of urea together with a more or less constant but trivial albuminuria. The urine, the fluroscope, the opaque enema, and the actinogram, when combined in examination, may corroborate the revelations of each other so as to warrant an assertion that colonic repairs should be instituted at once. Whereas the absence of urinary findings merely shows that absorption or penetration is perfectly arrested by an intact epithelial barrier; and this no matter how much the actual form, the capacity, or the activity of the caput coli itself may depart from what is considered its usual state.

Many patients who require plication to relieve pain or other physical handicap have already been operated upon for some abdominal trouble, the sequelæ of which condition may render the caput coli rather difficult to find. Possibly it may be on the left side of the abdomen. Fortunately the longitudinal tæniæ form what is known as the tænial loop, which is not unlike that made by looping a piece of rather thick string. This may be felt by taking hold of the extremity of any caput coli with a crooked forefinger. It makes small difference whether that finger hook is pushed into the loop from one side or from the other; but if there is a choice perhaps the best method is an introduction that shall carry the posterior colon wall forward (upward) upon the finger tip, while the adjacent palmar surface of the same finger gently lifts the loop. Recognition is easy, the loop feels to the touch just as might be supposed in advance, and it is as unlike any other abdominal structure as possible. In fact, it is quite credible that skill from practice might make one so certain in placing the colonic loop that visibility, light, or darkness might become secondary considerations.

One need not drag upon the loop nor do anything foolish with it; but if he once becomes so familiar with it that he can get his finger hooked into it quickly, then it is very easy to push aside the ileum or other structure with a finger or two of the opposite hand that may be made to approach and clear the way directly to the finger-held loop without loss of time through visual search; and this whether the caput is adherent, or non-deliverable or not, for the loop remains a true guide to the caput, to the appendix, or to the stump that is left by a previous appendectomy, while the rubber-covered finger represents a maximum of gentleness when instrumentation is under consideration. It follows that the whole procedure is devoid of danger while it makes for less trauma by rendering laparotomy pads, sponges, their friction and pressure unnecessary.

One complication that is often found in colonic difficulties is due to back pressure that arises from obstruction caused by sharp or acute angulations in the sigmoid. When such is the case the rest of the colon is more or less distended with its transverse portion hanging in a festoon or loop that is below its usual level, in the upright position. After this condition has endured for some months or years the patient often begins giving a history of retained enemata. Much as though the angulations allowed the enemata to flow inward, but after that they took upon themselves the action of a check-valve and prevented any outflow. The cases referred to show capitally on a photo enlargement of a radiogram; but the reproduction here is better given by a mere outline without confusing or unnecessary details.

It is to be understood that these show anterior surface with the bend anteroposterior but the one-sided contraction is a curious mechanical obstacle to efficiency. These pictures are both from the same patient who had a colonic atonia little short of paralysis or complete inertia. The patient was watched carefully until his weight increased by seven pounds and then a well-vaselined lampwick tampon was inserted into the rectum, was worked carefully through the angulations and was left in position as any drain might be left. The longest

time that it remained where placed was 40 hours, with 28 to 30 hours as the usual. It drained fecal matter down into the ampulla so that when it did come away there was an average loss of seven pounds in weight before the bowel movements ceased again.

With the help and advice of Dr. Frink and the staff the writer repaired this colon at the Knickerbocker Hospital. After an appendectomy the colon was plicated, the ileo cecal valve was made tight, and then the rectum was dilated to its maximum extent so far as safety would permit. At this time the bowels moved freely, copiously, and with what the staff and nurses termed "projectile force."

This was a decided contrast to what they all knew of the case, because the day before operation an enema had been given without result. This was followed after a time by a second enema; but both first and second remained invisible or where they were put. It was all much as though rectum and colon were absolutely inelastic. After the bowels had ceased moving upon the operating table, the rectum, etc., were carefully tamponed. The patient promptly started upon what was euphemistically referred to as a very ambitious scheme of house cleaning, with much changing of bed linen. The nurse marked the chart as one dejection; but "going on all the time," as for the tampon it was not found because "we did not dare look for it"; but the

patient's complexion changed in appearance for the better with an improvement from his previous toxic state that showed almost from the minute that the operative work was completed. His temperature never reached 100°, he was sitting up in a chair on the fifth day, and he went to his home in good condition on the eleventh day. Therefore his recovery was what might be called "uneventful."

The resident physician did marvel "who was ever going to get that tampon out?" However, there need be no substantial worry on that score. There was no doubt in the minds of those present as to what the sigmoid with its angulations and their curious contractions would do or what they had done when the opaque enema had been introduced and photographed, some months before. Dr. Frink had seen the patient once upon a time in one of the Navy Hospitals and according to his recollection it was a general opinion that operative measures were not so very promising of success in a case of such long standing and with so pronounced an atonia. But when the doctor saw the patient again at the Knickerbocker he was quite surprised at the general improvement in appearance and in condition that had resulted from a year or more of purgative tamponade which had been employed about once a week during the elapsed time.

This tamponade is an old expedient. Its technic is as follows: A rather large gauze packer is selected; it is dipped into yellow vaseline so as to fill the lumen of the tube and then the filled tube is carefully worked up as far into the bowel as it may safely go. Anyone who has seen what an immense amount of bowel length may be strung upon a glass rod will understand that the depths, attainable by the process known as packing, depend largely on familiarity and care in the employment of that process. The soft metal packer may be bent in any desired direction; but after it is properly placed a strip of gauze two inches wide and twenty-four inches long may be inserted into the tube and may be pushed through with the stylet in the usual manner so that the gauze strip shall travel clear of the tube and shall be left in the bowel after the tube is withdrawn. The operator's finger is then inserted beyond the sphincter area and adjusts the previously inserted strip so that none hangs down into that area and so that the whole strip is above the internal sphincter and outside of the grip of its contractions.

It will be found true upon observation that the patient often does not know when the aforesaid strip passes owing to the mushy, soppy condition that obtains. The patient usually insists that he has had a bowel movement, but he is equally positive in his assertion that the strip did not come away along with that movement. If the attendant has any doubt on the question an examination of the rectum will remove it, because the fact is that the strip and first stool after placement pass out together; as any patient on the lookout will find, just as any patient not on the outlook will miss finding.

The longer the gauze remains in situ the better will be the result. It will rarely remain 48 hours, no matter how much one may wish to keep it in the bowel. Though it must be understood that the purgative tamponade is not intended as a substitute for either enema or purgative, but is a means of procedure with indications of its own. Within its limitations it has often proved itself an exceedingly useful expedient.

Dilatation and impotence of the caput coli are not synonyms, for it would seem as though an incredible amount of stretching of the circular fiber and bands may take place in the presence of splendid, thick, glistening, pearly, and altogether healthy longitudinal tæniæ. For the latter, in spite of an appearance of flawless soundness, will permit bulging of the napkin ring structures to the stage that the writer has denominated semi-hernia. The state of colon to be most feared, however, is the non-struggling, indifferent, and inelastic one, where tæniæ have atrophied or almost disappeared so that colonic action has become very sluggish indeed. In other words, the distended, but active and fighting colon is not at all so difficult to remedy as the placid, flaccid, indifferent, but smaller or less distended one, so that the stretched rubber-band condition gives a much quicker convalescence than does the flabby or wet dish-rag state. The stretched elastic colon wall returns so quickly to its normal when its thinned bulge is repaired and reinforced that the quickness of result is incredible even to beholders. Take the patient referred to in this paper. His letter written two weeks (14th day) after operation states that he has a daily movement before breakfast. This was a man accustomed to a perfect orgy of purgatives, yet without medicine he has an "alarm-clock" movement. To quote: "I met my doctor on the street to-day and he was surprised at the success thus far and also at my freedom from pain." The atonic, atrophied colon may not bulge much, but its tæniæ are hard to find and its postoperative return to activity is slow indeed. So that three months may be allowed as a reasonable time. It follows that, when the evidence warrants a colonic plication, that operation should be performed at once lest the conditions pass into the passive state of exhaustion and inelasticity.

Retro- and intra-peritoneal bodies are akin to enteroliths and though not at all rare they do not show well upon the actinogram unless they contain considerable calcium. If they are free and can be easily removed then their removal is advisable. If, on the contrary, they are retroperitoneal in position it is good practice to leave them alone if they are not in a position to do damage. A good example among the writer's cases has this *x*-ray report: "Two shadows appear in the pelvis, in the median line at the level of the fifth lumbar body and upper sacrum. Due to calcific deposits in abscess, tumor, or cyst." These were retroperitoneal, were quite movable and appeared to have plenty of room. One was on one side of the spine, one on the other. An attempt at removal, in view of other extensive surgery in the case, was discussed and considered unwarranted. Therefore colon and inflamed appendix, which were both on the left side, were attended to, were restored to something like the conditions that were desirable; but the calcific masses were left in situ, while a good and uneventful recovery took place. After all, the great interest that attaches to the abdominal stones is the error of non-recognition by radioartists, so that these bodies are reported as renal calculi, or, in fact, as almost everything imaginable except what they truly are.

Finally, there appears to be no more constant

accompaniment to colonic urinary evidence than the presence of ova of the eutozoa in the feces. Whether the eutozoa will damage the colonic epithelial shield depends solely on the resisting power of that particular shield.

128 West Eighty-sixth Street.

SURGERY OF THE NECK.*

By EDWARD G. JONES, M.D.,

ATLANTA, GA.

Interest in surgery of the neck has been greatly stimulated in recent years by three major factors. These are: (1) A workable understanding of what structures may be attacked or sacrificed; (2) a more intelligent appreciation of the lymphatic anatomy and drainage; (3) the brilliant development of thyroid surgery.

We have gradually come to know that one or both sternomastoids will not be seriously missed by the patient. Other muscles like the omohyoid, sternohyoid, sternothyroid, and digastric, when sacrificed, have their functions so largely assumed by other muscles that the deprivation is soon not a great inconvenience. The internal jugular vein on one side may be removed with impunity. The opposite jugular also may be sacrificed after a reasonable interval for the enlargement of collateral vessels. No apparent embarrassment follows the simultaneous ligation of both external carotids, though it is to be remembered that if the ligature be applied too near the bifurcation the clot in the stump may be dislodged and carried to the brain via the internal carotid. The necessity permanently to ligate the internal or common carotid is regretable—and fortunately rare; the risk (cerebral softening or hemiplegia) is much greater in the second half of life. Total ablation of the cervical lymph nodes entails no obvious ill effects. Unilateral section of the vagus, phrenic or hypoglossal nerve is unfortunate but by no means necessarily fatal. Comparatively few neck operations, however, seriously expose these nerves to injury, assuming even ordinary caution on the part of the operator. Their bilateral injury is a surgical calamity.

Vagus irritation causes more disturbance than unilateral section, varying from no effect to tachycardia, slow respiration, unilateral laryngeal paralysis, nausea and vomiting, dyspnea, and rarely death from heart failure of pulmonary congestion. Bilateral vagus section causes death by paralysis of the glottis and laryngeal muscles, cardiac exhaustion, respiratory failure, pulmonary edema, or pneumonia. Section of one phrenic allows relaxation of one-half of the diaphragm with collapse of the related lower lobe of the lung; partial compensation through intercostal nerve supply follows. Keen observes that section of both phrenics would probably not be fatal in man. Section of both hypoglossals usually results in fatal aspiration pneumonia. Section of the spinal accessory causes some drooping of the shoulder from trapezius paralysis, but the patient accommodates himself to the deformity without much inconvenience. The branches of the cervical plexus which skirt the posterior border of the sterno-mastoid are sensory and can be destroyed without permanent abnormality.

It is apparent, therefore, that under necessity almost any or all, of the paired neck structures may be removed on one side, and that many of them may be removed on both sides. Indeed, there is now no neck structure which is beyond sensible surgical attack.

It is perhaps not too much to say that the profession—even the surgical profession—does not fully appreciate the fact that the lymphatics of the neck converge to form one large trunk on the right and one on the left. On the right no lymphatic drainage fails to enter the right lymphatic duct; none passes onward to the throax or axilla or elsewhere. Likewise on the left, all the drainage from the lymphatic vessels of this side meets to form a single trunk which enters the thoracic duct; none drains beyond in an accidental or purposeless way.*

However relentless nature may be in penalizing the cervical glands in the ordinary course of such affections as malignancy about the face or mouth, and tuberculous invasion by way of the tonsils, she nevertheless has provided the anatomical arrangement just mentioned for surgeons to see. When we have sensed the significance of the truth that, starting at the base of the neck, one *can* remove all the lymphatics *en masse*, very much as one would an offending breast; when we reflect that, having removed all the glands and gland bearing tissue, no fear need be entertained that the operation is still futile on account of probable mediastinal metastasis—then we are justified in taking courage and doing a really helpful, though extensive, operation instead of the half-hearted and haphazard surgery which assumes a recurrence and invites failure.

In case of malignancy if one has not misjudged the extent to which he ought to carry the dissection; and if he completely removes all the lymphatics in the area of necessity there will be no local recurrence; the recurrence, if such there be, will be from late dissemination by the blood vessels. On the other hand, intrathoracic neoplasms do not drain into the neck glands. Involvement of cervical tissues secondary to such growth is explained on the basis of (1) reversal of the lymph current incident to blocking, so that the infection backs up into the inferior deep cervical glands from the thoracic duct (or right lymphatic duct) through the trunk entering it in the neck, or (2) of embolic vascular transportation—both of which are a part of the general dissemination of advanced cancer. The occasional involvement, for example, of the left supraclavicular glands in the late history of gastric carcinoma is an apparent exception to this statement; but this phenomenon is like-

* Presented by invitation before the Medical Association of Alabama, Anniston, Ala., April, 1920.

* The right jugular trunk was found by Grossman to empty into the vein without being joined by the subclavian in twenty-four out of twenty-five subjects; junction with the broncho-mediastinal trunk was still less frequent. The left jugular trunk usually empties into the terminal thoracic duct, the subclavian and broncho-mediastinal trunks emptying directly into the vein.

wise taken as evidence of dissemination by one of the methods just mentioned*

Of course it is understood that there is normal drainage from the *chest wall* into the inferior deep cervical glands, as witness the frequent involvement of the supraclavicular glands in breast cancer,

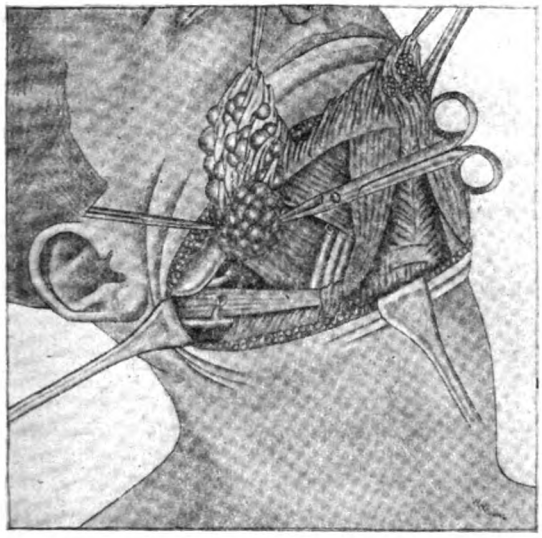

FIG. 1—Dissection of the submaxillary and submental regions.

either directly or indirectly through the axillary nodes.

Moreover, it is to be remembered that there is fairly free communication between the lymphatics of the two sides in the upper half of the neck, very little in the lower half. Likewise, while the lymphatics of one side of the tongue drain to the lymph nodes of that side they may drain also directly to those of the opposite side. This arrangement renders a unilateral resection of the upper cervical lymph glands in cancer always unsafe and always reprehensible.

Cancer of Lip.—The lymph vessels from the upper lip run to the submaxillary nodes. Those from the outer aspects of the lower lip run likewise to the submaxillary; but those from the center run to the submental modes. Now the ducts to the submaxillary glands do not asnastomose, those to the submental do (Morris.) This latter statement is significant. It renders unilateral submental resection futile; clinically unilateral submaxillary resection is extremely hazardous.

Secondary drainage from the submental and submaxillary nodes into the deep nodes is easy. In operating, if the submaxillary glands are plainly involved on both sides it must be assumed that all the deep glands are already cancerous. This, of course, at once raises the question of operability—not because the deep glands cannot be removed, but because of the probability that cancer cells have passed the last defensive line, entered the blood vesse.s, and so escaped beyond surgical reach. If operation is undertaken it should begin at the base of the neck, and unless everything is made subservient to thoroughness it need not be done. All the glands, deep and superficial, including also the sternomastoid muscle, must be removed *en masse.* The jugular vein may be resected or left. We feel that the dissection can be done a little more quickly by removing it. If it is left the utmost care must be exercised not to leave small glands lying close to it. Both jugulars should not be removed at the same time. The block dissection can usually be done more expeditiously than one would think, and in cancer cases more quickly than when we are hampered with the usually extensive inflammatory reaction about tuberculous glands.

The mere diagnosis of cancer of the lip condemns the submental and submaxillary glands on both sides. This is a rule of practice to which no exception ever is allowable. The dissection must include the submaxillary salivary glands because a few small lymph nodes are so closely associated with them that the sacrifice is necessary. The submental nodes not infrequently lie concealed by the anterior bellies of the digastrics and are too commonly overlooked (Fig. 1). Experience vindicates the leaving of the lymph vessels between the tumor and the lymph nodes. Recurrence in the tissues between the lip and the glands is extremely rare—a tribute to the view of embolic dissemination.

FIG. 2—Dissection showing removal of deep cervical lymphatics with sternomastoid.

If the removed submaxillary and submental glands are not plainly involved and do not show microscopic cancerous involvement (the frozen section being examined immediately) one may be satisfied to leave the deep glands. If the removed nodes of one side are found to be cancerous the

* However, there is about this explanation something that is far from satisfying. The natural metastasis of cancer is admitted to be embolic—not by thrombotic extension along the walls of the lymph vessels. But that cancer cells should be transported in the current of the thoracic duct (the natural course of metastasis from the mediastium or stomach) and enter the trunk draining into the thoracic duct from the supraclavicular glands *against the current,* and with no apparent reason for blockage beyond the junction, is strange. Likewise, it is incredible that *vascular* implantation should be here to the relative exclusion of other localities. Thrombotic growth along the walls of the duct is more probable.

operation must include the deep glands of that side.

Cancer of Tongue.—The lymph drainage from the tongue is treacherous.

The anterior drainage is into the submental glands by one set of vessels. There is another set which, passing the cornu of the hyoid bone, follows the posterior (upper) border of the omohyoid, and enters a node lying on the internal jugular at the point where it is crossed by the omohyoid.

The lateral drainage is into the submaxillary glands and into the upper deep glands about the internal jugular and common facial veins.

One of these latter, the "chief gland" of Cuneo, situated on the internal jugular beneath the posterior belly of the digastric, is the most important single gland to be considered in connection with cancer of the tongue, since it frequently, if not usually, receives drainage from the posterior as well as the lateral part of the organ.

The posterior drainage is into the deep nodes of the upper neck. Moreover, in the posterior half of the tongue the collecting lymph vessels frequently cross the midline so that infection from one side will drain not only to the nodes of the same side, but also to those of the opposite side.

It is evident, therefore, that in operations for cancer of the tongue we can never afford to stop with removal of the submaxillary and submental nodes, as we may sometimes do in cancer of the lip. Even when the lesion is at the tip of the tongue we must remove the deep glands as far down as the crossing of the omohyoid over the internal jugular vein. Moreover, it is never safe to leave the submaxillary or the deep superior glands on either side.

A surgical plan whose execution contemplates the removal of all the cervical glands with the gland bearing fascia and the removal of the floor of the mouth and tongue should be executed in more than one stage unless it be by an occasional surgeon of superlative skill. To attack the problem from below, so as to block lymph drainage as promptly as possible, and remove the tongue last is the better judgment.

714 Hurt Building.

ANOMALOUS SIGMOID SINUS THROMBOSIS WITH REPORT OF CASES.*

By JOHN F. BARNHILL, M.D.,

INDIANAPOLIS, IND.

It often happens that the most difficult task of the surgeon in the conduct of an aural case is exact diagnosis. This is especially true of sinus thrombosis, which apparently may vary in its symptomatology, from the presence of all but one marked symptom to all the symptoms that occasionally feature the typical case of this serious disease. The family physician, and even the otologist, too often, no doubt, expects the full array of symptoms before strongly suspecting sinus thrombosis in a given patient. The accumulation of facts in the form of case reports and personal experiences leads to the positive belief that, should the development of even a majority of the classical symptoms of sinus thrombosis be awaited before arriving at a diagnosis of this disease, most cases would go on to fatal termination. It would seem, judging by the rather large accumulation of data on the subject, that few, if any, other serious diseases vary so much as does sinus thrombosis in its outward manifestation of clearly defined phenomena of its presence. From a partial review of the literature, and from my own experience in determining the presence of sinus thrombosis in atypical patients, it seems certain that many cases have been overlooked in the past. It probably would be helpful, therefore, to emphasize what is undoubtedly a fact, namely, that sinus thrombosis as manifested by clearly intelligible symptoms is perhaps more often atypical than classical.

Day, Friedenwald, Welty, and others have reported cases in which thrombosis was present without fever. It would seem incredible that infection of so large a blood vessel, or of its contents, could take place without high temperature, but statement of facts by these accurate observers cannot be disputed. Furthermore, a careful study of the methods of formation of the clot in the vein show the possibility of such an occurrence. Emerson has reported three cases in which there was fever, but in which the temperature was atypical because much lower than would be expected in this disease—101-102°.

Many case reports show atypical sinus thrombosis in that there is an almost complete absence of ear symptoms. The rather common belief that there must be present a discharging ear, mastoid tenderness and great pain should be revised. Especially should emphasis be given to the fact that swelling and tenderness of the neck along the course of the internal jugular vein are rarely present, and only in the late and fatal cases. In my own experience of 37 cases of sinus thrombosis mastoid tenderness has been absent in nearly 50 per cent., and in one only, a case that was septic generally, partially unconscious and near death, was there swelling of the neck along the vein. In only five of my cases have there been actual chills. Chilly sensations have usually been present, but this fact is ascertained only by carefully watching the patient, and by frequently quizzing the attendants concerning the point. Strabismus and other eye symptoms have likewise been rare. Only 16 of my patients were examined for optic neuritis, and but two of these had choked disc, a rather low percentage since Crockett reports that 25 per cent. of his cases had choked disc, while Jansen states 28 per cent. and Jobson records two-thirds of all cases.

The presence of aural discharge is not a necessary symptom, as shown by the case of Robert Lewis and others, and by the appended report of a few of my own atypical cases. Occasionally a case is met with in which the aural discharge is absent, or apparently absent, and no history of former discharge can be obtained. Numerous cases of this class are reported. I had one such case, a patient 62 years old who persistently denied ever having had a discharging ear. After long deliberation of the whole family it was finally recalled that there was a history of discharge from the ear 60 years previously, since which time hard pieces of "ear wax" were occasionally removed from the canal. A plug of material resembling ear wax was present

*Read before the American Otological Society, Boston, June 2, 1920.

at my first examination, which, on removal, was covered with pus at the distal end. The drum head and ossicles were gone, the patient was suffering from severe headache and fever, and at operation fluid pus filled the lateral sinus and jugular vein. Until my examination the condition of the patient's ear had never been connected in any way with his illness, although he had suffered many weeks.

There is another type of case in which there either has been no discharge at all, or in which the discharge has been trivial and has continued for only a few hours or days. Robert Lewis reports a case in which there was no discharge at all, and had been no discharge. The cases which I here report had each an acute and trivial otitis which lasted but a few hours or days, was then either forgotten or disregarded, and was later not connected with the serious illness which followed.

CASE I.—Female, age about thirty, while in a hospital awaiting confinement was attacked by earache which lasted a few hours and was followed by a slight serous aural discharge, which continued only one day. Childbirth followed very soon, after which the mother continued feverish and prostate for about six weeks, at which time I saw her for examination. Several physicians and one excellent general surgeon were in attendance, and from these and from the bedside chart I obtained a very complete history of the case. The patient apparently suffered from nothing except a septic temperature and the resulting prostration. It had been assumed by the physicians in attendance that the confinement had in some way caused the continued illness, but every effort to locate any pelvic or breast affection had been negative. Repeated blood count always showed a high leucocytosis, running as high as 20,000. No blood culture was made. Excellent *x*-ray plates of the head, sinuses and mastoid had been taken, which all agreed were normal. There had been no distinct chill, no unusual sweating, no headache, no eye-ground or other eye disturbance. Mentality and the reflexes were undisturbed. There was, indeed, no symptom, except fever, which ranged between 99° and 105°. After some quizzing concerning the ears I obtained the history of a slight earache six weeks previously and of a trivial aural discharge lasting for a few hours. On examination the drum-head was nearly normal and was free from inflammation. Hearing was slightly impaired. There was no evidence of any recent discharge. No tenderness was present over the mastoid or neck. All aural evidence was negative.

In view of the aural discharge six weeks previously, of the continuous septic temperature, and of the statements of trained physicians that on repeated examination no general body affection could be found, I expressed the opinion that sinus thrombosis was probably present and that exploration of the mastoid and sinus was justified.

At operation the mastoid antrum and cells were found but little if at all diseased. The sinus from behind the knee to near the jugular bulb was filled with liquid pus. The internal jugular vein was widely exposed, was ligated high up and low down, and was excised. It was blocked by a firm clot just above the entrance of the facial vein, and above the clot was creamy pus. The stumps of vein were dropped back into the wound, and, as is my plan always, the wound was closed, excepting the lower angle, where a small gutta percha drain was left for twenty-four hours. The patient made a speedy recovery.

CASE II.—Boy, aged nine, was seen first by me in a distant country home, March 12, 1916. The family physician stated that the boy had been ill about one month, and that his chief symptoms were a slightly discharging ear, a continued high temperature, and the resulting prostration. The temperature, which was recorded twice daily, ranged from normal to 105°. There was never any chill, pain, vomiting or other symptom indicative of intracranial complication. The discharge from the ear had been slight and differed in no way, as stated, from other harmless discharges which the doctor had often seen. The continued high temperature could not be accounted for. There was, the doctor was positive, no lung or other involvement that could produce the fever. The little patient had been dieted and the bowels had been cleared without effect. It was thought that the ear might be the cause, but the symptoms referred to this region were, he thought, so trivial as to make this unlikely.

At the time of my visit the appearance of the patient was septic and somewhat anxious. He was greatly wasted. He made no complaint whatever of pain. His eye and general reflexes were normal. There was no tenderness, redness or swelling in or around the ear, and no evidence whatever of mastoid or other aural complication, except the slight aural discharge. The fundus of the eye was not examined. Owing to the isolated situation of the patient no blood examinations had been made. The temperature curve indicated almost certainly a bacteriemia, and, since no other assignable reason for such infection could be found by repeated examination, my belief was that probably a sinus infection and thrombosis were present. The child was therefore taken to a small hospital, where further observations were made, and these more strongly pointed to sigmoid sinus infection.

At operation, March 13, 1916, the mastoid structure was found broken down, and after the removal of a thick cortex with gauges the interior was easily exenterated with the curette. The sinus was widely exposed, and, on slitting it open, creamy, yellow pus poured out under pressure. The mastoid wound was covered and isolated from the neck, preparatory to resection of the jugular vein. The vein was exposed from about the third tracheal ring to near the mastoid tip, and a portion resected, including the facial and superior thyroid branches. An organized clot filled the upper portion of the jugular. The septic symptoms, following the operation, speedily subsided, appetite returned, and the child soon returned to normal vigor and health.

CASE III.—Boy, aged nine, admitted to hospital March 23, 1918. He was referred for middle ear trouble, and had not been very well previous to this illness, having had German measles one month before. The mother said that he had scarlet spots over the breast at the onset. He now had a goood deal of desquamation of the skin of the hands and fingers, the skin coming off in rather large strips; and a rather dry skin over the rest of the body, which will probably desquamate in little fine scales. A typical raspberry tongue, which previously was thickly coated. Patient having been carried twenty miles in an ambulance during a raw day, complained of slight chilliness on admission. Temperature 101°, pulse 96. No complaint of any kind, no headache, no pain, no nausea. Fever, weakness and a slight discharging ear were the only subjective symptoms. On physical examination there was a septic appearance. The eyes were normal to superficial examination. No appearance of acute suffering. There was a moderate amount of thick pus in the external auditory meatus, but this was in no way different from the discharge found in any acute running ear. There was not the slightest mastoid swelling, redness or tenderness. Mentality was normal, considering the condition of fever. The temperature rose to 103.5° five hours after admission. Next day the highest point reached was 100.8°. The two succeeding days it rose to 103° and then for five days the highest point was 100.6°. The next day, the eighth after admission, 102° was reached, and then for two days remained almost normal. On the eleventh day a rapid rise took place, on the twelfth day reaching 104°. On the thirteenth day the mastoid was opened and the sigmoid sinus was widely exposed and incised. The sinus was filled with creamy, yellow pus, which, under pressure, poured into the mastoid wound when the sinus was opened. The jugular vein was exposed, ligated and excised as in Case No. II. The temperature after the operation at no time exceeded 99°, and no symptom arose which hindered speedy recovery. The child left the hospital April 25, nineteen days after the operation, in almost perfect physical condition.

The blood count ran as follows: On the third day after admission W. B. C. was 17,400; on the sixth day, 26,600; on the seventh day, 22,000; on the ninth day, 21,400; on the eleventh day, 13,000; on the thirteenth

days (mastoid and sinus operation), 11,600; on the fifteenth day, 12,400; on the seventeenth day, 14,400; on the eighteenth day, 13,600; on the twenty-first day, 13,800.

One week after admission to the hospital the slight aural discharge, which had been daily growing less, ceased altogether. At no time while under observation was there present any pain in or around the ear, nor was there any mastoid swelling or tenderness. The mastoid region at all times, judging from the painstaking examinations which were made daily, was entirely normal. There was no sagging of the posterior wall of the external meatus, and, after the aural discharge ceased, the hearing improved. Eight days after admission there was soreness in the neck which disturbed the boy's rest, as it was difficult for him to find a position which gave comfort on the pillow. The neck muscles were quite tender, but on examination of the throat it was found that this external tenderness was due to a throat infection, and this finally proved the case, for when the throat improved the stiffness and soreness of the neck promptly disappeared. Had careful examination of the throat not been made this case might improperly have been reported as one in which there was tenderness of the neck as a symptom of jugular involvement in sinus thrombosis. On the ninth day in the hospital a cough came on, which continued for a week and proved very annoying, and a mild central pneumonia was disagnosed by a consultant internist.

At no time during the entire hospital period was there any nausea or vomiting, any headache, mental disturbance or pain, with the exception of the painful neck muscles, as above described. Indeed, I regard this case, as the preceding ones, entirely symptomless in so far as the recorded symptoms pointed to sinus thrombosis, with the exception of the trivial aural discharge and the temperature curve.

CASE IV.—Report of Dr. John M. Fouts, the family physician: "Howard S., aged thirteen, came to my office, May 1, 1920. Had some pain in right ear. A thin pus was running from ear. No tenderness of external ear or over the mastoid. Made firm pressure against tip of mastoid without complaint. Temperature nurmal. Appetite good. Boy was doing the work of a boy of his age on the farm.

"Had measles and whooping cough in February of 1911, with otitis media as a complication. After the first few days of his present illness the pain subsided, but the slight discharge persisted. At times nothing but dry scabs could be removed from external ear. The acute exacerbation of May 1 was caused by a mild bronchitis, according to the history given by the parents. The pain this time was very slight, scarcely mentioned by the patient. He assisted with the farm work until May 9, but lost in strength; was called to see him on this date. Was then confined to his bed with a temperature of 104° F., pulse of 100. Right ear discharging, no pain or tenderness over mastoid or neck. Lungs, heart, and throat negative. Tenderness in right iliac fossa and marked gurgling over same area. Had some pain over eyes. No diarrhea, but was susceptible to laxatives. May 10. Morning temperature 102°, pulse 98. Slept well, no appetite, no pain, tongue coated and moist. Evening temperature 104°, pulse 100. May 11. Morning temperature 102°, pulse 100. Evening temperature 105°, pulse 100. Complained of headache. Talked in sleep. Mind confused when aroused. Perspired some during the night and said he was chilly, but no distinct chill. No pain or tenderness in ear or over mastoid. May 12. General condition same; no appetite, but took a reasonable amount of nourishment. Drank water very freely. Was sick at stomach once during night. More delirious at night. May 13. Temperature and pulse same. Some headache. Some swelling below right ear, which was tender. Mother said he had had this before. The first time that there had been any tenderness about ear. The left elbow was swollen and very tender. May 14. Temperature 100° in the morning and 104° in the evening; pulse from 100 to 110. Muscles of back and back of neck contracted, but patient could get out of bed. Mind clear during the day and wanted to sit up. Ear discharge thicker and of bad odor, creamy. No pain or tenderness. Operation still refused and the patient declared he would rather die than go to the hospital. May 15 and 16, patient losing. Dr. J. F. Barnhill called May 17, and patient removed to the hospital May 18."

At the time of my visit the boy seemed deeply comatose, but when aroused answered questions with some intelligence. There was a stupid look when asleep. The eyes seemed normal in every way. There was no complaint of pain, but extreme irritability concerning any disturbance was evident. There was a slight discharge from the ear, which was foul smelling. No pain or swelling in or around the ear or neck, except that due to enlarged cervical nodes. There was no pain on deep pressure over the mastoid. Stiffness of the nuchal muscles was present to a degree that enabled me to lift the head and trunk entirely from the bed without any flexion. A large spindle-shaped, red and tender swelling involved the left elbow and the right knee. The abdomen was very tympanitic. Owing to his stupid condition it was difficult to determine the knee and other reflexes with accuracy.

In view of the absence of any lung or heart complication, and of malaria or typhoid fever, the diagnosis was probably sinus thrombosis. This seemed especially probable, too, since five years previously I had removed the boy's tonsils and adenoids, and at this time there was present a chronic discharge from the ear, due to the measles in 1911. I had stated to the mother at the time of the adenoid and tonsil operation that the ear probably would not be cured except by radical mastoid surgery. After the tonsils and adenoids were out, however, the aural discharge ceased and was almost forgotten. It was necessary, according to the mother's statement, to give no further aural attention than occasionally to remove what she thought were large plugs of ear wax.

May 19 the patient was transported a distance of 75 miles to a hospital in Indianapolis. The journey was not difficult, but on arrival the condition was much worse, neither food nor drink having been taken since the day previously. There was complete unconsciousness. Temperature, 102°; pulse, 100. Blood culture showed a short chain streptococcus. This was transferred to a blood agar plate, which twelve hours later showed a streptococcus growth, with complete hemolysis around the colonies—a beautiful demonstration of Streptococcus hemolyticus. Blood count on admission was W. B. C., 18,400; polynuclears, 83 per cent.; small lymphocytes, 10 per cent; large lymphocytes, 6 per cent; transitionals, 1 per cent.

An expert internist again went over the case and gave the positive opinion that there was present no general disease. The boy's parents were anxious now to have a surgical operation, even though the prognosis was bad, and was so stated frankly to them.

At operation a thick, hard cortex was rapidly removed with gouge and mallet, the interior of the mastoid being easily cleared with curette and rongeur. The cells contained pus and débris. The sinus was widely exposed. Near the tip of the mastoid the sinus wall had ruptured, and through the opening creamy, foul-smelling pus poured out under pressure. It is my belief that the pus encountered in the mastoid cells at operation came from the sinus. The mastoid wound was covered and isolated, the jugular vein was quickly exposed, ligated above and low down, and the intermediate portion was excised. No clot or pus was found in the jugular.

On cutting down on the jugular vein a row of matted, half-suppurating lymph nodes were found, overlying the carotid sheath. It was necessary to remove these to get access to the vein. It was these inflamed glands, undoubtedly, and not the jugular vein itself, which had caused tenderness on pressure of the neck, reported by the family physician. The boy died four hours after the operation.

A question of clinical importance is, was this sinus infected and suppurating while the boy was in his usual health, and while actually at work on the farm? It is my belief that such was the case. Five years previously, as already stated, there was present a chronic suppurative middle ear with mastoid involvement. While the mother states that the suppuration ceased, and that the boy was well, she further states on quizzing that the boy frequently picked at the diseased ear and sometimes removed large plugs of ear wax. This

"wax" was dried pus, showing that the suppuration, while less than formerly, and not sufficient in quantity to run from the ear, represented a slowed-down but nevertheless continuous, progress with fatal termination.

PENNWAY BUILDING.

THE PRINCIPLES OF ADRENAL SUPPORT.

BY HENRY R. HARROWER, M.D.,

GLENDALE, CAL.

THE adrenal glands, small pads of endocrine tissue lying above each kidney, exert a very important influence upon those functions of the organism which are beyond the control of the will—the automatic or sympathetic regulation.

Among other things it is the function of these glands to regulate the tonicity of unstriped muscle, including that of the heart, blood vessel walls, and alimentary canal. In fact, all muscles, voluntary and involuntary, are affected by the adrenal principle, which is called "adrenin." The adrenals also are concerned in the regulation of the cell chemistry, as well as the harmonious function of the other associated glands of internal secretion.

These glands are influenced very decidedly by toxic substances which may get into the circulation. As a matter of fact, it is the function of the adrenals to respond immediately to toxic stimuli in order that the body's defensive and detoxicating mechanism may be started in its necessary work as soon as possible. As the result of this the administration or release of various poisons causes an increase in the work of the adrenal glands with circulatory changes which are very well known, as well as other changes in oxidization which are made necessary by the toxemia.

Since poisonings of various varieties are among the commonest causes of disease, *the adrenal element has a much greater importance than the medical profession has given it credit for.*

During the influenza epidemics the unusually severe toxemia resulted in serious depletion of the adrenals in many thousands of cases, and brought attention very forcibly to the importance of the adrenal glands as maintainers of the tonicity of the body. Not merely influenza, but all acute infectious diseases and the accompanying toxemias, as well as all chronic foci of infection, are common factors in over stimulating the adrenal glands. If the glands were not stimulated the body's defences against these conditions would not be initiated properly, and death would ensue.

It happens that the adrenal principles, especially adrenin, are very easily oxidized by the body, and there must be a continued supply of this principle in order to maintain the sympathetic and automatic functions of the body in proper order. If these glands are excessively stimulated, like any other organs of the body, they become tired out or depleted; and sometimes the degree of depletion is very marked, just as the degree of fatigue may be marked following severe exertion. As a result of this adrenal insufficiency, or hypoadrenia, there ensues a condition which is the result of the absence of the all-important stimuli expected from this gland.

Hypoadrenia is quite similar in its symptomatology to the more serious structural disease of the adrenals which was described by Addison in 1855. Addison's disease is believed to be a destruction of the adrenal glands, usually by tuberculosis, while the hypoadrenia to which attention is being directed here is a functional playing out of these glands due usually to the toxic stress referred to.

The symptoms of adrenal insufficiency are asthenic in character. In fact, fatigue is the principal result, and it may be of a most severe variety. The patient is tired out and unable to accomplish his usual mental or physical work. He has an aggravated degree of muscular fatigue which extends to the involuntary muscles causing heart weakness (very commonly these cases are classed as "myocarditis" when in reality there is no real structural change in the heart muscle at the time), the vessel walls lose their tonicity and as a result there is a condition of low blood pressure which, in turn, causes cold hands and feet and other evidences of circulatory insufficiency.

The muscles of the alimentary canal are equally atonic, and as a result we find constipation, indigestion, and the well-known intestinal stasis. Parenthically it may be stated that the toxemia from intestinal stasis is just as much a cause of adrenal stimulation as that which results from any other poisoning, and consequently the adrenals are still further depleted with still more atonicity. A vicious circle is produced.

Neurasthenia, or nervous break-down, is very commonly the result of adrenal insufficiency, not merely because of the ever accumulating poisoning, the result of the general atonicity of the body; but because of the direct influence upon the nerves. They, too, have lost their normal tonicity and are asthenic, just as the rest of the body is asthenic. Many forms of neurasthenia may be connected with other glands of internal secretion, especially the thyroid or the sex glands; but the most commonly involved of all of the endocrine glands undoubtedly are the adrenals, and practically every case of neurasthenia is of an endocrine character, and involves the adrenal glands.

Perhaps the most important of all the asthenic manifestations of adrenal insufficiency is what I have personally called "chemasthenia." By this I mean an asthenic state of the cell which causes metabolic laziness or cellular inefficiency. The chemistry of the cells most vital in its influence on the body is lessened, and the cells are unable to eliminate their own waste products. Consequently they cannot avail themselves of the food substances that are brought to them by the blood. This causes malnutrition and added toxemia which is of very serious import. Chemasthenia is invariably present in severe cases of adrenal insufficiency, and the urinary analysis, especially the study of the 24-hour output of urea, will indicate very promptly whether there is a deficiency of this kind.

Oftentimes the eliminated urea is reduced as much as two-thirds of the usual normal, and, naturally, the accumulation of these wastes in the body does not favor the best of health. Since most of the wastes of the body have an acid influence, that is to say, they remove from the body the reserve of alkaline salts which is kept on hand for just this purpose, demineralization and a tendency to acidosis is the rule in all these chronic cases.

Prof. W. B. Cannon, of Harvard University, has demonstrated quite conclusively that emotional factors stimulate the adrenals. Fear, rage, pain, and other emotions, including probably worry, act upon the adrenal glands almost identically as do toxins, and adrenal depletion from shock or mental storms is almost as common as that due to actual poisoning. Hence, the frequency of hypoadrenia is really very great, in fact *I believe that it is the most common of the endocrine disturbances.*

It is not difficult to diagnose hypoadrenia. The patient invariably complains of a marked lack of "pep," and is "all run-down." "'Asthenia' is their midde name." They are tired all the time; and mentally, physically, and physiologically these unfortunate individuals are worn out. There is evidence in the history of a chronic or acute toxemia, or there is other clinical proof that the fundamental causes which deplete the adrenals have been present. The blood pressure in most cases is considerably below normal; sometimes it has reached as low as 80 mm. systolic. The elimination of urinary solids is low, and nutrition ordinarily is reduced. As a result of this, anemia is not uncommon and the patient's powers of resistance are considerably less than usual, and they are subject to all sorts of aches and pains and discomfort of a functional type.

It just happens that most of these cases with hypoadrenia are in the large class to whom the average physician prescribes a tonic. Now, most of the tonics are of the strychnine type, that is, they are alkaloidal poisons and are tonics in that they stimulate the adrenals to produce more of its chemical substance and thereby to increase circulation, muscular tone, and nervous tone. In cases of adrenal insufficiency, however, the adrenal glands have had all the stimulation that they can stand and are played out. Therefore the administration of strychnine or similar substances is merely a means of aggravating the already serious adrenal insufficiency. For this reason strychnine and alkaloidal tonics, including coffee, should never be given to an individual with depleted adrenals. The idea is to remove as best we can all sources of toxic stimulation of these glands, to allow them to rest as best they are able, and to support them in a manner which I will now describe.

It is well known that organotherapy is dependent very largely upon a fundamental principle described by Prof. Hallion, of Paris, which is called "the law of homostimulation." This is as follows: "Extracts of an organ exert on the same organ an exciting influence which lasts for a longer or shorter time. When an organ is insufficient, it is conceivable that this influence augments this action, and when it is injured, that it favors its restoration." This homostimulation is not at all comparable to the stimulation that results from strychnine. As a matter of fact, organotherapy is the supplying of a suitably prepared and all ready-to-be-used pabulum that can be made available and used at once by the cells that correspond to those from which the extract was made. In other words, adrenal support by means of adrenal substance is a satisfactory means of antagonizing hypoadrenia, just exactly as the administration of thyroid substance to the person with thyroid insufficiency is likely to modify the conditions which are due to a lack of the thyroid hormones.

The administration of adrenal substance is known to exert a musculo-tonic effect. It slows, steadies, and strengthens the heart; it raises the blood pressure and, by actual measurement, increases the elimination of wastes. Therefore, adrenal support by means of adrenal therapy is a rational means of modifying the results of hypoadrenia, and with it, of course, other things may be done simultaneously that are equally advantageous. Chief among these is the removal of all forms of toxemia—from foci of infection, from the alimentary canal, from the food ingested, and from any other source that can be discovered and modified. Add to this remineralization, which means the administration of suitable alkaline mineral salts to replace those that are deficient in the body. To build up a reserve of alkalines is always in order. Still further, the cellular influence of other endocrine preparations which cooperate with the adrenal glands very properly may be made use of.

Practically every individual who is suffering from adrenal insufficiency also has a greater or less degree of hypothyroidism. At all events, oxidization is deficient, and every effort that can be made to increase the cellular activities of the body is a rational one. Small doses of thyroid are helpful in accomplishing this, for it is well known that the thyroid also is important because of its power to increase cellular chemistry and to favor detoxication. Hence, in many cases of hypoadrenia small doses of thyroid gland, perhaps a quarter of a grain a day, may be added to adrenal feeding.

Still another endocrine product is used with great success in conditions of the adynamic type. I refer to spermin, the endocrine principle from the interstitial cells of Leydig of the sex glands. Spermin is a muscular tonic; it stimulates muscular contractility and also the chemistry of the muscle cells, and perhaps other cells also. It has been recommended for many years as a means of increasing "pep" and the general tone of the body; and is distinctly called for in the cases of muscular asthenia so commonly associated with adrenal insufficiency. For many years I have used a formula containing the above mentioned products in cases of this sort.

In conclusion, I urge the consideration of the adrenal aspect of the every-day disorders which come to our attention. Since asthenia is so essentially a symptom of adrenal origin, let every history which embodies this most common statement prompt us to investigate the factors mentioned above which are believed to be related to adrenal functioning. If the asthenia is accompanied by low systolic tension, subnormal temperature, low 24-hour urea and solids, and a tendency to acidosis, the diagnosis is clear. The development of the history will have given reasons for this adrenal depletion, and its treatment should be added to every effort to modify the toxic or infective causes, as well as the other indicated hygienic and eliminative measures. Adrenal support is a rational adjuvant measure in the majority of the cases which come to us from day to day.

HORATIO C. WOOD, M.D.

AN APPRECIATION.*

By HENRY BEATES, Jr., M.D., Sc.D.,
PHILADELPHIA.

By the death of Prof. Horatio C. Wood the medical profession and mankind in general have suffered an irreparable loss. His life was an example of sincerity of purpose, diligence, honest endeavor, and justice, and an exceptionally powerful influence for the uplift, growth, and development of those sciences with which he was identified. Endowed with an unusual mind, and insatiable in the acquisition of knowledge, the ever conspicuous power and faculty of learning were demonstrative of his great intellect.

Indefatigable as an investigator, utilization of time and opportunity found him ever active in the study and solution of problems presented by the various natural sciences to which his life was dedicated.

The eagerness with which he engaged in study was a conspicuous characteristic, and illustrated by the following incident that occurred when a mere youth: Visiting the Philadelphia Academy of Natural Sciences and standing before a locked cabinet containing specimens in which he was deeply interested, and being unable to handle and examine them, his disappointment found expression in tears. The great Leidy passing by, and noticing the distress of the youthful Wood, inquired the cause. Being informed, and doubtless recognizing the impulses of genius, he had the cabinet unlocked and the specimens placed at the student's disposal.

Dr. Wood was an enthusiastic student of botany. In 1860, when but 19 years of age, he presented his first scientific paper, entitled "Contributions to the Carboniferous Flora of the United States." From then until 1873 fourteen papers, each of which was an authoritative classic, appeared in the Proceedings of the Academy of Natural Sciences, the American Philosophical Society, the Queckett Microscopical Club Journal, the Smithsonian Institute, and in the *American Journal of Science*. In 1872 the Smithsonian Institute published Dr. Wood's monograph, "The Fresh-Water Algæ of North America." This 270-pp. quarto contained 19 colored and 2 uncolored plates, prepared from 360 original microscopic drawings which, for accuracy of detail and perfection, are unsurpassed. It remained the authoritative work on this subject for 25 years.

Demonstrative of Dr. Wood's phenomenally acute powers of observation and consequent ability to recognize and discover new species, the following botanical papers may be mentioned: "Life History of Some Siphonaceous Fresh-Water Algæ," "Manner in Which *Schizomeris leibleinii* Produces Its Zoospores, and New Species of Desmids," "New Species of the Genus Sirosiphon, *S. lignicola, S. phloiophilum, S. disjunctum.*"

Entomology also engaged his attention during these years, and his achievements in this branch of science culminated in fourteen papers characterized by that thoroughness and masterful research which stamped each as an authoritative contribution and an acquisition of knowledge. Of these studies, which want of time prevents naming, that entitled "The Myriapoda of North America" was published in the American Philosophical Society Transactions in 1865. It was a brochure of 112 pages, with 61 figures in the text and 3 plates. The drawings, true to nature, were exponent of his skill. The excellence and reliability of his work was recognized by Louis Agassiz, who in 1865 headed a large naturalizing expedition to Brazil, and, after his return, wrote the following letter to Dr. Wood:

DEAR SIR:

While in Brazil I have collected a good many myriapods in every part of the empire visited, and I will gladly put the whole at your service as soon as the specimens can be picked out, but I cannot say how soon this will be possible, as I cannot make a beginning with the arrangement of my collections before I can secure the means of buying about 5000 gallons of alcohol to carry the work through.

Very truly yours,

AGASSIZ.

Dr. H. C. Wood.

Dr. Wood was an indefatigable worker. He would frequently concentrate his mind upon the subject in hand for 30 consecutive hours; then relax and indulge in an uninterrupted sleep of from 12 to 18 hours, when his insatiable thirst for knowledge found him again active in the pursuit of investigation and discovery, with that intensity of interest and painstaking care in observing the minutest details which crowned his labors with phenomenal success.

Profound learning necessarily established a high plane from which to observe conventional standards of achievement, and enabled Dr. Wood to enter his chosen profession of medicine with a mind exceptionally well informed, and an intellect of superior power.

As professor of botany in the Auxiliary Medical Course of the University of Pennsylvania, his ability as a teacher was highly cultivated, and his occupancy of the Chair of Materia Medica and Therapeutics in the major faculty of medicine constituted one of the strongest and most influential chairs of the then famous center of medical education. He was a brilliant and impressive lecturer and a teacher of great renown.

Dr. Wood's career in the natural sciences rendered him extremely alert in recognizing the inevitable consequences of cause and effect. He was painfully conscious of the imperfections and limitations of empirical medicine, and the measure thereof found expression in the fearless manner in which, then almost single handed, he entered the arena in a struggle having for its aim the establishing of physiologic or rational medicine upon a firm and scientific basis. With an open mind, ever alert to recognize and acknowledge truth, he did not belittle the knowledge of means to end that empirical medicine had established, but sought to add thereto elucidation and explanation. His sincere willingness to entertain and accept demonstration of mistake or error was parallel with his eagerness and desire to guide and instruct and guard against error wherever and whenever encountered, and the measure of his true greatness. To Professor Wood belongs the honor of having been a pioneer in establishing the Epoch of Rational Medicine. The

*Read at the annual meeting of the American Therapeutic Society, held in Philadelphia, May 7 and 8, 1920.

courage of conviction that found him alone championing rational medicine, *i. e.* therapeusis based upon knowledge and logical conclusion, was conditioned upon the recognition of the defects of empirical medicine. From the first edition of his epoch-making treatise on Therapeutics published in 1874, and antedating that of Lauder Brunton by 10 years, of which 14 editions were printed, and have served as a model for text books on Therapeutics in European countries, as well as in the United States, the following quotations from the preface serve to emphasize the firm foundation upon which he stood:

> There are a number of excellent treatises upon Materia Medica and Therapeutics, yet in various attempts at original research, as well as in the ward and lecture room of the hospital, I have keenly felt the want *of something more.* The old and tried method in therapeutics is that of empiricism, or if the term sounds harsh, of clinical experience. The best possible development of this plan of investigation is to be found in a close and careful analysis of cases before and after the administration of a remedy, and if the results be favorable the continued use of the drug in similar cases. That very much has been thus accomplished it were folly to deny. Therapeutics developed in this manner cannot rest, however, upon a secure foundation. Looking at the revolutions and contradictions of the past, listening to the therapeutic babel of the present, is it a wonder that men should take refuge in nihilism, and like the lotus eaters, dream that all alike is folly—that rest, and quiet, and calm are the only human fruition? A primary knowledge of the end to be accomplished, and a secondary acquaintance with the instruments, are a necessity for human effort, and until the sway of this law is acknowledged by physicians, medicine can never rise from the position of an empirical art to the dignity of applied science. The work of the therapeutist is with the second portion of the law. Evidently it is his special province to find out what are the means at his command, what the *individual drugs in use do when put into a human system.* Thus did the champion and pioneer of Rational Medicine enter the arena of controversy and withstand the attacks of relatively ignorant and emotional antagonists who sought by all means available, social, financial, and political, to prevent scientific investigation, and the establishment of the Era of Rational Medicine.

Animal experimentation was a *sine quâ non* which was most bitterly opposed. No less an authority (an authority, however, in another sphere, be it remarked) than the famous Niemeyer asserted that experiments made with medicaments upon lower animals, or upon healthy human beings have, as yet been of no direct service to our means of treating disease, and that a continuance of such experiments gives no prospect of such service. The antagonists asserted that medicines did not affect lower animals as they did human beings. Apparently the contention was well taken, but Dr. Wood demonstrated that while apparently this was true, in reality it was erroneous, and a misinterpretation. He proved that while it required as much morphine to kill a pigeon of a pound weight as to destroy a man, it was not a different action, but on the contrary, an identical one, the seemingly different effects being dependent upon varied degrees of susceptibility, and that the modus operandi was identical. This physiological law or truth Dr. Wood further demonstrated by a study of atropine. Contrasting an animal which may be exceedingly sensitive to the spinal action of atropine with one in which it exerts its effects upon the conducting fibers of the nerve trunks, we find it causes convulsion in one and paralysis in the other. This law makes understandable why so many drugs seemingly exert an antagonistic action. Dr. Wood, by conclusively demonstrating that degree and quality are *two separate and distinct things, and should never be confounded,* successfully combated the efforts of ignorance and emotionalism to make it a crime to pursue scientific research. What may be properly designated as the magnum opus of Wood, the institution of an epoch in medicine characterized by the relinquishment of the empirical and the adoption of the rational, and of establishing an era conspicuous for achievements in preventive as well as curative medicine, is sufficient to place his name side by side with those of the immortal Hippocrates, Galen, Sydenham, Hunter, Lister, Laennec, Jenner, Pasteur, and Koch.

In 1810 Majendie, studying the effects of nux vomica, recognized the vital importance of knowing how medicines affected the human system, but to Prof. Horatio C. Wood belongs the credit of having brought to the recognition of the medical world the necessity of adopting physiological or rational medicine as the one essential means of acquiring knowledge and skill and art in the prevention and treatment of disease upon which humanity depends.

Dr. Wood consecrated himself to medicine. In 1869 he made his famous experiment upon himself with American grown cannabis. The following year his first paper on the "Physiological Action of Drugs" was published in the *American Journal of the Medical Sciences.* His studies of the action of veratrum viride led to its general adoption by clinicians. In 1871 Dr. Wood's papers treating of the physiological action of amyl nitrite were published. Two years previously Lauder Brunton published his paper which set forth the value of amyl nitrite in angina pectoris, but the contribution of Dr. Wood was the first description of the physiological action of the drug upon the nervous system. His investigations of chloroform, ether, and other anesthetics, are so well known that mention only is necessary. These results were published in 1890, and the following year found him honored with being selected to make the principal address before the general session of the International Medical Congress at Berlin. These studies have probably been responsible, more than the work of any other scientist, for the general adoption of ether as an anesthetic by the entire surgical world. It was while pursuing the studies of anesthetics and the treatment of their toxic effects that Dr. Wood discovered the value of strychnine as a respiratory stimulant, and its importance in averting threatened death.

Of 5,000 scientists present at the Berlin Congress the Duke of Bavaria, a physician, selected and entertained 25 who were noted for exceptional achievements. Of these Professor Wood was one, and when about to be seated the duke, removing his crown, placed it upon Dr. Wood's head, and further honored him by requesting him to occupy the chair pro tem. Thus Professor Wood was a Duke of Bavaria for almost an hour.

In 1903 Dr. Wood represented the United States Government at the International Conference, held in Brussels for the purpose of unifying the more important preparations of the various pharma-

copeias. Early in its session the conference became so involved in acrimonious dispute as to the proper percentage of alcohol to be used in making tinctures that the whole usefulness of the meeting was seriously threatened. His strong personality and recognized advocacy of justice and right enabled him to convince the delegates of the foolishness of quibbling over minor details, and they finally adopted the present regulation of 10 per cent. tincture and various other standards which are recognized by the pharmacopeias of practically all civilized nations. This busy practitioner, teacher, investigator, and author published a text book on nervous diseases and their diagnosis in 1887, and of the 240 medical papers, each one of which was a classic, and an addition to the knowledge of the science and art of medicine, the treatise on thermic fever, or sunstroke, has especial value. Published in 1872, it was accorded the Boylston prize. That this work has contributed to the saving of thousands of lives annually is an evidence of one of the great services this man of genius has accorded to humanity.

His investigations of fever culminated in a work of 250 pages, which was published by the Smithsonian Institute in 1880. It is a monument to his learning and a most valuable contribution to medical science. Dr. Wood discovered the alkaloid hyocine while studying the effects of hyoscyamine, and in 1885 demonstrated its value for certain nervous diseases.

His researches in experimental pharmacology, physiology, and pathology embody more than fifty contributions of knowledge to the science and art of medicine.

Twelve conscientiously elaborated subjects of medical jurisprudence and toxicology which were, as all of his works, instructive and of great practical value, were contributed from the years 1873 to 1899.

As a clinician, his studies of pathology, medicine, and therapeutics comprise 139 papers, which for originality and profundity of learning are invaluable. Thirty-six published lectures and addresses appeared in various journals during the years from 1874 to 1900, and extended his beneficial influence throughout the continent.

Nine magazine articles from the year 1872 to 1879 brought to the lay mind information and knowledge which proved of great value in securing popular cooperation with efforts instituted by the profession for the betterment of standards of medical efficiency. In 1875 there appeared in *Lippincott's Magazine* an article contributed by Dr. Wood entitled, "Medical Education in the United States." This paper brought to a crisis the agitation which had been active for many years concerning this matter, which was and is of such vital importance to the profession of medicine, as well as the greatest and highest interests upon which human welfare is conditioned. It caused radical changes in the medical department of the University of Pennsylvania, and indirectly compelled other colleges of medicine to reform their curricula. It advocated State board examinations, and was a powerful influence for the establishment of the legal supervision of the qualifications and rights to practice the healing art.

In 1889 Yale University conferred upon Professor Wood the degree LL.D. The occasion was made an opportunity for Dr. Wood to use his influence in promoting and intensifying interest in higher medical education. The title of his address, "The Medical Profession, the Medical Sects, the Law," emphasized the necessity of demanding for the doctorate men of proper preliminary education, and the administration of an ample curriculum. The too commonly encountered unfitness of clinicians upon whom colleges had conferred the medical degree and the fearful consequences of this, he emphasized by the astounding statement that the horrible disasters of the Johnstown flood were insignificant when compared with those resulting from the illy prepared and unqualified practitioner. So strongly was Dr. Wood convinced of this seriously inadequate but then prevalent system of medical education, that the comparison was unhesitatingly presented to the interested audience with that vehemence which characterized his advocacy of higher ideals.

'Tis the habit of action that individualizes man, and imparts special qualities to his charcter. That "Nature never rhymes her children nor makes two men alike" is a fact that explains why men of genius constitute a center from which emanate influences for either good or evil that powerfully modify the lives of all within their range. That Dr. Wood was keenly alive to this great truth is made manifest by his definition of character. "Character is the established equilibrium existing between the emotional, the intellectual, and the volitional" are his words. To establish and possess that equilibrium is an achievement which few attain. It taxes to the utmost the noblest and best qualities with which a man is endowed, and that Dr. Wood was ever alert to so do was evidenced by his every action. Once, while in conversation, he suddenly stooped down and caught a large roach that was crossing the floor, and holding it in his hand, fondled it. Being asked why, his reply was that to master a baseless dislike of anything harmless was invaluable, and when it caused one to overcome empty prejudices, it contributed to the usefulness of being and did much to give force to one's influence for the betterment of fellow-man.

Dr. Wood was profoundly conscious of the value of time, and as a superficial glance into his active life shows, every moment was advantageously occupied. As an example of untiring and continual work he stands preeminent, and the fundamental principles underlying his achievements are well shown by the subject of his inaugural address before the trustees, faculty, and student body of the University of Pennsylvania, when as professor of Materia Medica and Therapeutics his wonderful career in that capacity began. He urged upon every one that a definite object in life be the goal for which to strive, and that substantial progress is conditioned upon a thorough mastery of each involved factor. In that manner by which he had the happy faculty of impressing great truths upon the minds of his pupils, he drove home these principles by quoting from Mother Goose, how leg over leg the dog got to Dover, and all who were privileged to hear him proclaim how the dream of his life was to become a professor and that by a conscientious mastery of minute and upbuilding details the goal

was reached, were doubtless stimulated to emulate the great teacher and strive to do their best.

As Emerson so impressively states, character is the moral order seen through the medium of an individual nature. An individual is an enclosure—time and space, liberty and necessity, truth and thought are left at large no longer. All things exist in the man tinged with the manners of his soul. With what quality is in him he infuses all nature that he can reach, nor does he tend to lose himself in vastness. He animates all he can, and he sees only what he animates. He encloses the world as the patriot does his country as a natural basis for his character and a theater for action. A healthy soul stands with the just and the true as a magnet arranges itself with the pole so that he stands to all beholders like a transparent object betwixt them and the sun, and who so journeys toward the sun journeys toward that person. He is thus the medium of the highest influence to all who are not on the same level. Thus men of character are the conscience of the society to which they belong. To the honor and memory of the great and first president of the American Therapeutic Society may be justly ascribed the consummation of a life conspicuous for moral, intellectual, and physical excellence, the influence of which for betterment activating the thousands emulating his example will continue on and on anon. His life will ever serve as a guide and stimulus for right living, and constitute a power for good in the uplift of humanity as lasting as time.

260 South Sixteenth Street.

THE GERM-PLASM.

By CASPER L. REDFIELD,

CHICAGO, ILL.

THE germ-plasm is the living material from which the next generation of things is produced. It is the substance of the germ which is separated from the parent and which grows into a new individual like the parent. The doctrine of the "continuity of the germ-plasm," which dominates the biological world at the present time, is that when a bit of this germ-plasm is separated from the parent, part of it is used to produce a new individual in the second generation and part of it is set aside as a reserve in the body of the new individual to become later the origin of an individual in the third generation. When a bit of this reserved germ-plasm later leaves the second individual of the series, part of this bit is used to produce an individual in the third generation and another part is set aside in this individual to become the starting point of a fourth generation. And so on.

According to this theory, the germ-plasm resides in the adult individual but is not a part of the adult, and is not descended from it or from any previous adult. A mother and her daughter arise at different dates from the same continuous stream of germ-plasm, and are sisters rather than mother and daughter in the ordinary sense. The germ-plasm does nothing but reproduce itself, from a part of which another individual is started into existence. As the part which starts a new individual does not go back again to become a part of the general stock, it follows that the part which is held in reserve is descended from a long stream of germ-plasm which never did anything except grow and reproduce itself.

When we reproduce a plant by a cutting, that cutting will grow into a new plant which in due course will produce seeds, and from these seeds we can start a new generation. As a seed without germ-plasm will not grow, and as the germ-plasm is supposed not to be produced by the plant, it is evident that a supply of the germ-plasm must have existed in the cutting which was taken from one plant to produce another. As such cutting may come from a root or branch, or even from a leaf, it follows that the germ-plasm which forms no part of the adult must be distributed uniformly through all parts of such adult. It is supposed to pervade the entire body without being a part of it.

In this matter we have to deal not only with a physical body designated as the germ-plasm, but we have to deal with the powers of that body to produce individuals having many powers. There has been much said about the "physical basis of heredity," but very little about the nature of the powers that basis must have if it is to function. We will give a little attention to the power side of this problem.

It is known that powers are developed by exercising them, and that they degenerate when there is a failure to exercise them or when they are exercised less than some minimum amount per unit of time. For example, when a man takes up physical training he develops the powers of the muscles he exercises, and these powers continue to develop as long as the exercise is continued, up to some point near the end of life. When a physically active man takes up a sedentary life, his physical powers gradually decline, and that decline in powers continues as long as a failure to exercise continues.

When a horse is trained at the trot year after year he will continue to gain in trotting power as long as the trotting exercise continues. Race track records show such improvement up to seventeen years of age, and other evidence shows that it will continue under continued exercise up to the evening of life. When a race horse is retired to the harem and thereafter leads a physically indolent life, his physical powers decline, and continue to decline as long as the indolence continues.

It is known that the blood reaction of different kinds of animals is different, and that a micro-organism which can live in the blood of one animal is unable to survive in that of another. Most micro-organisms are able to exist in the bodies of only a few kinds of hosts.

Experiments have shown that when smallpox virus is taken from a human patient and inoculated into a cow, it will take only about once in ten trials. In fact, the smallpox germ can survive in the cow only when it comes to some cow which, from some cause or other, happens to be in an unusually weak condition at the time. But when this organism has once succeeded in its fight for life in the blood reaction of a weak cow, it has built up its powers by its own efforts in fighting that kind of blood reaction and then can be passed along to and can live in a cow in whose blood it would have died if inoculated there in the first instance. Then it can be passed along from cow to cow in series, and each

time it thus passes it further builds up its powers of fighting the blood reaction of cows by exercising such powers.

While the smallpox germ is thus busy developing its powers of fighting the blood reaction of cows, it is not fighting the blood reaction of man with the result that if it be inoculated into a man after having passed through a series of ten or twelve cows, it is found to be cowpox and not smallpox. It has lost the power of fighting the blood reaction of man by not exercising that power, and is able to survive only a short time in that blood reaction. And a man who is vaccinated builds up his powers of resisting smallpox by beginning his exercise on a weak form of it, with the result that he becomes able to resist fully virulent smallpox when it later puts in an appearance. But after he is vaccinated he ceases to exercise his powers of fighting smallpox virus because there is none present to fight, and the result is that these powers gradually decline. If he is to continue to be able to resist smallpox he must again exercise the powers he has by again being vaccinated.

Here we have a case of one kind of power being built up in the protoplasm of a germ by exercising that power, and simultaneously another power in the same protoplasm was permitted to decay by reason of a failure to exercise it. Also, we have the case of resisting powers being built up in the bodily cells of the man by exercising such powers as he had at the time, and subsequently the decline of the same powers in the same person by a failure to exercise them for some years.

When disease-producing bacteria are raised on some artificial food, as bouillon or agar, they do not have to fight a hostile blood reaction, and as a consequence they gradually lose their disease-producing powers by failing to exercise them. By putting such weakened bacteria through a course of training in which they are forced to use these powers to a gradually increasing extent, their virulence can be increased to something greater than it was when they were first placed upon artificial food. These facts were first found by Pasteur in working on the anthrax bacillus, and have since been found by other persons working on other germs. From the mass of evidence bearing on this matter we will consider here only Haffkine's work on the cholera bacillus.

He wanted two grades of this organism for vaccination purposes. He found that the bacilli obtained from the intestinal canal were too powerful for the preliminary inoculation and not powerful enough for the secondary one. He got the weak strain by raising the bacilli on agar, and found that it would remain weak just as long as he continued to raise them on artificial food. He got the powerful strain by passing the germs through a series of about thirty guinea pigs, and then found that they rapidly lost their power when placed on artificial food. To maintain the powerful strain in powerful condition he found it necessary to pass them, from time to time, through a series of guinea pigs.

Haffkine then inoculated guinea pigs with the weak culture, and several days later with the powerful culture. Both inoculations caused local swellings and a rise in temperature, but these soon passed away, as neither inoculation was great enough to be an overload for the system. A guinea pig treated in this way was found to be able to resist from eight to ten times what was the lethal dose of cholera poison for untreated guinea pigs. Pfeiffer found that the power developed in the guinea pig by this process was one which would first kill and then dissolve the cholera bacillus.

Man has domesticated many kinds of wild plants and by training them in various ways has caused them to develop their powers of producing the things he wanted. But while he has been doing this he has protected them from weeds so that they would not have to fight for room in which to grow. Because our domestic plants have not had to exert themselves in a fight for existence against weeds they have lost the power of so fighting and are not now able to survive when deserted by man. There is no selection in this. Man did not select plants because of their inability to defend themselves against weeds.

A seed is an inert object, but it contains germplasm and has the power, under proper circumstances, of developing into another plant like that from which it came. At least it has that power when it is first produced. But let that seed lie idle two, three, four or more years, and that power gradually declines and finally ceases to exist. The germ-plasm (the physical basis of heredity) is still there, but it has lost its power of developing into a new plant because of a failure to exercise that power for a considerable length of time. The loss of powers by reason of a failure to exercise them applies to the germ-plasm just the same as it does to the somatoplasm.

When we first attempt to raise a plant from cuttings we frequently find it difficult to make it grow in that way. But if we take a cutting from the first plant grown from a cutting we find that it grows a little easier the second time than it did the first time. If we take a cutting from this second plant we find that it grows still easier the third time, and so on time after time. There is no selection in this because no seeds are produced. The final plant is simply a section of the original plant, but its powers of growing from a cutting have been greatly developed by exercising them over and over again.

But a plant which is continually raised from cuttings is not raised from seed, and consequently is not exercising its powers of growing from seeds. It may be exercising its powers of producing seeds, but the powers of producing seeds and the power of growing from seeds after they are produced are two different things. Now it happens that all plants which are continually reproduced by cuttings, grafts, tubers, or divisions of any kind, and not by seeds, gradually and certainly lose their power of producing seeds which will germinate, and ultimately lose the power of producing seeds at all. The germ-plasm cannot retain a power which it does not exercise, and it cannot transmit a power which it does not have.

The sequoia are the oldest of living things. They are said to be from one thousand to two thousand years old, perhaps older. They produce abundance of seeds because they have been exercising their seed-producing powers regularly year after year. But it is extremely difficult to make those seeds

grow, and apparently they will not grow at all from the older trees. Right here is a distinction which the reader should get clearly in mind. A man does not get strong muscles because his brother goes into a gymnasium. The germ-plasm in seed produced this year by a sequoia does not have its powers of germinating developed by the exercise which was gone through by the germ-plasm in some sister seed produced by the same tree a thousand years ago. The last time, genetically possible, that the germinating powers were exercised was when the parent tree grew from a seed. Even in trees of such tremendous vitality as the sequoia, the germ-plasm loses powers which it does not exercise for a thousand years or more.

It is well known to breeders of cattle, horses and dogs that a young sire is more potent in the production of offspring than are older ones. This does not mean that the older sire produces a less number of spermatozoa. It means that those produced by the young sire have greater powers of uniting with ova and growing into new individuals, and less powers of some other kinds. The last time those powers were exercised was when the sire was produced by the germ-plasm derived from his parents, and the longer the idle period between one exercise and the next the more do those powers decline. In human beings of the same family, it is found that the sons of young parents are more prolific in the production of offspring than are the sons of older ones. This fact was determined by comparing brothers in family genealogies.

Let us now return to the doctrine of the continuity of the germ-plasm. According to that doctrine, the germ-plasm which is supposed to produce the new individual never, in all of the ages, exercised the powers of producing such an individual. But when we investigate the matter we find that when the germ-plasm fails for a considerable period of time to exercise any power it has, that power gradually declines and finally ceases to exist. As the germ-plasm actually has the power of germinating and growing into a new individual, it is evident that that power must have been exercised either directly by that germ-plasm or by some substance from which it was derived. And as the germ-plasm also has the power of transmitting to the new individual all of the powers exercised by the somatoplasm, it is evident that the germ-plasm must be condensed somatoplasm or the extract of somatoplasm. The continuity of living substance is a certainty, but the continuity of the germ-plasm is a physical impossibility. It cannot function.

Medicolegal Notes.

Question of Hospital's Care in Safeguarding Delirious Patients.—While all the authorities hold that a private hospital owes to its patients such reasonable care and attention for their safety as their known mental and physical condition reasonably requires, yet this is always limited by the unbending rule that no one is required to guard against or take measures to avert that which under the circumstances is not likely to happen, or, more accurately, which a reasonable person under the circumstances would not anticipate as likely to happen. The law only requires reasonable care—that care to avert dangers which a reasonable man would take under the circumstances as they exist—and no man does or is required to take measures to avert a danger which the circumstances as known to him do not suggest as reasonably likely to happen. These circumstances include the patient's mental condition and aberrations, and what he is likely to do by reason thereof, the degree of his mental and physical helplessness, and the dangers which his surroundings afford. Under these rules the Missouri Supreme Court held in Breeze v. Railroad, 264 Mo. 258, 174 S. W. 409, that hospital attendants were not required to anticipate that a patient who was delirious and possessed of delusions, but showed no tendency to self-destruction, would throw himself out of a high window, and was not required to guard against such action. The same court in Phillips v. Railroad, 211 No. 419, 111 S. W. 109, held that the attendants of a mentally helpless patient should anticipate that such patient, if allowed to go unattended on the streets of a city, would likely wander onto a street car track and receive injury and should guard against such danger. In Robertson v. Towns Hospital, 178 App. Div. 285, 165 N. Y. Supp. 17, the court held that it was reasonable to anticipate that a patient suffering mental derangement from alcoholism would throw himself out of an open window when he had exhibited the delusion that some one was trying to kill him, from whom he was trying to escape, so, also, the court in University of Louisville v. Hammock, 127 Ky. 564, 106 S. W. 219, held that a patient similarly afflicted, the nature of his ailment being known to the attending physician, might reasonably be expected to become violent and dangerous at any time, and consequently that his liability to injure another patient should be guarded against. In Hogan v. Clarksburg Hospital Co., 63 W. Va. 84, 59 S. E. 943, a patient was injured by his wandering to an open fire and his clothes catching fire. The court said that the hospital was bound to exercise "that degree of care towards its patients placed therein measured by the capacity of such patients to look after and provide for their own safety."

In Torrey v. Riverside Sanitarium, 163 Wis. 71, 157 N. W. 552, the court said that it could not reasonably be anticipated that a mentally deranged patient, possessing delusions as to his heart and stomach, but tractable and showing no symptoms of violence, would suddenly break away from the attendant and injure a third party. In Harris v. Woman's Hospital, 14 N. Y. Supp. 881, a woman patient, in a fit of temporary insanity, threw herself from a window. She had shown some symptoms of mental derangement. In denying liability the court said that her death in this manner was not to be expected. In Wetzel v. Omaha Maternity Assn., 96 Neb. 636, 148 N. W. 582, where a delirious patient fell out of an open window, liability was upheld on the ground that the patient's condition and previous conduct were such that a tendency to self-injury might well have been foreseen and should have been guarded against. In an action for the death of a patient on the third floor of a hospital, who, while in a delirious condition and while attempting to escape from the hospital, fell to the ground and was killed, the Springfield (Mo.) Court of Appeals holds that the defendant hospital's negligence was a question for the jury.—Davis v. Springfield Hospital (Mo.), 218 S. W. 696.

Disease or Accident as Proximate Cause of Death.—In an action on a policy covering bodily injury sustained through accidental means the petition alleged that the insured having a wound in his side caused by an operation for appendicitis, from which he had fully recovered, an embolus from some accidental cause became attached to the wound, that while lying in bed propped up with pillows, the insured slipped off the pillows, and the jar of his body, incident to this fall, separated the embolus from its lodgment on the surface of the wound, and was taken up by the blood and projected through the veins to the heart, resulting in the insured's death. It was held that the petition stated a cause of action, as against a general demurrer, and that the question whether or not the insured would have died at the time he did die if it had not been for the alleged accident was for the jury.—Pacific Mut. Life Ins. Co. v. Meldrim, Georgia Court of Appeals, 101 S. E. 305.

SYMPTOMATOLOGY OF CANCER OF THE MIDDLE EAR.

THE onset of cancer of the ear is frequently silent and it is only after an otological examination that a suspicion of malignant growth may arise. In these circumstances the patient will probably seek advice for a discharge from the ear dating back to childhood; polypi obstruct the fundus of the tympanum and after removal they soon recur. It is only on this account that a microscopical examination is usually made, but this should always be done in the first place and then an early diagnosis of malignancy may be made. Occasionally, it is true, an ordinary polypus may show an otitic proliferation and lead one to suspect cancer, but in simple polypus the proliferation is invariably in contact with the surface epithelium, while in cancer the masses are more isolated one from the other. If the process is malignant, the polypi are more friable, with rapid recurrences and frequent hemorrhages. In some cases the pain is severe and is the reason for the patient seeking medical advice, and although not a constant symptom it is rarely absent. It occurs in paroxysms and these are so violent that they are difficult to support. A discharge invariably exists whether it precedes the neoplastic development or is the result of a secondary infection. Absence of an internal suppurating process has been rarely observed and almost always the growth succeeds to a chronic discharge. At the commencement, the discharge is slight but it increases in amount, becoming profuse, fetid, and often bloody, containing necrotic débris. The growth quickly extends and is not long in invading the surrounding bony areas, producing destruction of tissue to a far greater extent than the worst cases of cholesteatomata.

Paralysis of the facial nerve is the rule in all neoplasms of the middle ear and bony portion of the external auditory canal. The anatomical disposition of the nerve along the wall of the tympanum and bony canal, after its reflection, exposes it often at an early date in the process. Vertigo—a sign of destruction of the labyrinth—is a usual symptom which arises sooner or later as the morbid process invades the semicircular canals, and Zeroni has recorded the case of a patient who consulted him for vertigo from this cause, who always fell on the side of the ear involved. The vertigo may be due to irritation and compression of the brain from intracranial extension of the neoplasm. From the very onset of the growth, subjective sounds may be complained of, with frequently a decrease of the auditory acuity which may reach absolute deafness if the labyrinth is involved. The integrity of the latter may exist, yet the deafness will, nevertheless, be absolute from compression on the fenestra of the labyrinth.

The growth continuing its destructive action develops in various directions. If the entire ear is involved necrosis of the bone occurs, either from pressure or from disturbances of the nutrition, following which extension into the temporal bone may occur. The necrosis extends beyond the walls of the canal, the roof and antrum of the labyrinth, while the middle wall and labyrinth often resist the destructive process. In one instance, Mathewson found the capsule of the labyrinth forming a sequestrum suspended on the auditory nerve. The neoplasm may extend along the base of the skull and neighboring parts of the neck, giving rise by compression to a clinical picture simulating bulbar paralysis or unilateral paralysis of the facial, glossopharyngeal, pneumogastric, and hypoglossus. When meeting the dura and the vessels, the growth appears to cease its progress, the dura becoming thickened and offering a barrier to the neoplasm.

The transverse sinus is often near the posterior wall of the auditory canal so that it may early become involved, but usually the vessels are occluded by thrombi so that hemorrhage is exceptional. The lymphatics are often involved, but metastases are relatively rare. Enlarged lymph-nodes are solely due to suppuration and infection, and the enlargement may be such that the pre- and retro-auricular nodes completely deform this side of the head. The growth may invade the parotid at an early date and also compress the facial nerve at this point. Invasion of the lateral walls of the pharynx may occur, provoking pseudo-abscesses or occluding the Eustachian tube. Cachexia occurs prematurely and progresses rapidly and is a good diagnostic sign in favor of malignant disease. After cachexia, meningitis is the next most frequent cause of death, while if the pneumogastric is involved death may take place from pneumonia or paralysis of the heart.

SUPERIMPREGNATION.

IN a lecture on this and allied subjects before the Law School of the University of Rio de Janeiro (*Revista Medico-Cirurgica do Brazil*, May, 1920, xxviii, 5) Dr. Carlos Seidl said that multiple pregnances are the inevitable result of fecundation of two or more ova, and with the exception of twin pregnancies are very rare. It is commonly assumed in multiple pregnancies that fecundation has occurred almost synchronously. In law it is the first child to be born who is deemed the eldest, but in right it should be the one in whom which fecundation first occurred. In multiple pregnancy the children suc-

ceed one another at short intervals but in rare cases one is not born until after the lapse of weeks or even months. This is known as superimpregnation and the presumption is that different ovules have been impregnated and in different acts of coitus, even possibly by different fathers.

Superimpregnation is of two sorts, superfecundation and superfetation. The former requires only that there be different ova and different acts of copulation, but the interval is reasonably short. In superfetation the woman, in a more or less advanced pregnancy, conceives again while there is a fetus actually in the uterus. The former is regarded as quite possible, the latter as impossible. The reasons are first that every alleged case of superfetation admits of another explanation such as bifid uterus or death of one fetus long before term, with the other fully developed. These false superfetations are common enough and as a rule readily recognizable. Even in twin pregnancy there may be notable differences in fetal development. Clinically considered, the cases are also explicable by some other theory than superfetation, such as latent gestation, where for some reason one twin is not viable at the birth of the first. Nevertheless some leading obstetricians have had cases which could hardly be explained save by the theory of superfetation.

Theoretical reasons against superfetation comprise the cessation of ovulation and the impossibility of ascent of the spermatozoids to the tube. Superfetation has never been shown to occur in animals although superfecundation can be experimentally brought about. This is easily proved by allowing males of different strains to cover a female at different periods, in which case the character of the offspring will show the double paternity. In the human race it has been noted in the case of a negress who had cohabited with white and colored men during the same period of ovulation, that twins have been born, one negro and one mulatto. Facts of this type have been reported in the West Indies by both English and French writers. Pinard reported a remarkable case of twin pregnancy in which one child was sound and the other syphilitic. He impressed the woman greatly by assuring her that one child was begotten by the husband and the other by her lover, and she confessed. In the laws of various nations relating to legitimacy are some which would make illegitimate any child born later than 300 days after separation from the husband and in such a case both true and false superimpregnation could come up for expertisation. Ordinarily a second labor at a later period should raise suspicion of some form of bifid uterus. Many conditions might come up in obstetrical practice, as when a woman has married very shortly after the death of her husband, in which case with some irregularity in gestation and labor the question of superfetation could come up. Professor Tronge of the Chair of Obtetrics at the University of Rio supposes a case in which the second marriage took place 50 days after the sudden death of the first husband. The woman had borne a child one month before this second marriage and if pregnant in both halves of a bifid uterus might give birth again as late as 8½ months after her second marriage, provided she had been impregnated just before the husband's death.

THE DYSPEPTIC ORIGIN OF NIGHTMARE AND PAVOR NOCTURNUS.

THAT a difficult digestion will often give rise to disagreeable dreams is well known to all who practise medicine. Nightmare is a disagreeable dream, accompanied by a feeling of oppression and pressure over the epigastrium, terminating in a distressing awakening, the forehead moist and the limbs cold. Besides the epigastric distress and starting out of sleep, nightmare is characterized by the homogeneousness of the mental visions that constitute it, occasionally even by their stereotyped nature and the persistency of the painful remembrance. After the evening meal the patient is frequently overtaken by somnolence which he rarely has the courage to overcome; he goes to bed early under the impression that this impulse to sleep will continue. But very shortly he experiences a sensation of weight which binds the epigastrium, then this sensation rises to the brain and nightmare occurs, usually of such a painful nature that the subject awakens in a start. The most common types are a feeling of falling with a sudden start out of sleep and a cry, pursuit by an enemy, or a sensation of crushing by a heavy weight. Spitta has recorded the case of a female novelist who was in the habit of partaking of a heavy meal immediately before retiring when she desired to provoke horrible dreams in order to have material all ready on the following day for descriptions in her stories. The eminent English physician, Whytt, was himself a hypochondriac and has left us an admirable account of the extraordinary sensations he experienced when his stomach was "out of order." At the time this occurred and he was disturbed by wind, he was often attacked by mild nightmare. He would arise at once and as soon as he was completely awake it always seemed to him as if there was a weight over the stomach or that something impeded him in the gastric region, and this sensation was accompanied by languor or a kind of oppression. Whytt at length found that a small glass of brandy was both a prophylactic and curative of the condition.

Robin believes that to dyspepsia is due the majority of cases of the singular condition known as pavor nocturnus that has been so well studied by West, Henoch, Comby, and others. It is a common experience to meet with dyspeptic children who—large eaters and drinkers—suffer from pavor nocturnus. In these subjects it cannot be maintained, as some believe, that the process is a larvate form of hysteria or epilepsy because a proper diet will put a stop to all the trouble. Unquestionably, nervous children are more prone to develop these nocturnal accidents, but dyspepsia is in itself quite

enough to develop them. The phenomenon occurs from two and a half to three hours after the evening meal. The child awakes suddenly, rises in bed, with the eyes open in a fixed stare. He sees animals or robbers, cries for his parents, but does not recognize them when they appear. Neither caressing nor consoling words comfort him, but after the lapse of a few minutes to half an hour a parxoysm of weeping occurs, sometimes with involuntary micturition, but convulsions never occur, and the child then falls asleep. Attention to the diet and the exhibition of simple medicaments to correct the dyspepsia constitute all the treatment necessary to cure the patient. It is a therapeutic error to resort to the administration of bromides and sedative medication.

Syndrome of Bloch.

In the Medical Record for December 2, 1916, xc, 23, Bloch published an account of a syndrome which comprised hyperthyroidism with pseudo-hysteria. In *El Siglo Medico* for June 5, 1920, lxvii, 3469, Juarros reports the case of a "curious variation" of the disease picture, as follows: The patient was a woman of 28 years without hereditary or personal pathological antecedents. She had never required medical aid. A relative died and her husband had to journey from Madrid to Argentine to collect the inheritance. The patient, who was much upset by the separation under such conditions, wept incessantly and was unable to sleep for some nights. Little attention was paid to her, as the manifestations were regarded as ordinary grief, whereas in reality a neuropsychosis had begun. She became worse and her attitudes, gestures, and speech became pompous and affected. She sought to dominate the other members of the household, showed much irritability and began to smash crockery and do other arbitrary and unconsidered acts. The diagnosis of the attending physicians varied from hysteria to neurasthenia but her periods of violence were such that the family began to desire her segregation. At this juncture it was found that a hyperthyroid syndrome had developed—tachycardia, perspiration, hot flushes—to which appeared to be added ovarian insufficiency which led the author to the diagnosis of Bloch's syndrome. She was given ovarian preparations and antithyroid serum in ampoules and in two months was well. The typical Bloch syndrome is said by its discoverer to occur in young widows, divorcées, and others whose sexual life is violently interrupted. The chief symptoms are insomnia, irritability, attacks of weeping, asthenia, exaggerated vanity and pretentiousness suggesting paranoia, sensitive breasts and ovaries, abnormal pigmentation suggesting Addison's disease, dysthyroidism and dysovarism, gastroenteric symptoms, etc., the affection yielding to opotherapy.

The Prognosis of Fractures of the Metacarpal Bones.

Fractures of the metacarpal bones, although not frequent, are certainly not uncommon, especially in adult males; but women, elderly subjects, and children are less liable to these fractures. They are produced by direct or indirect violence and are sometimes the consequence of tearing away of the bone by the radial tendons. Their symptomatology is reduced to pain, swelling, echymosis, functional impotence, deformity, and crepitation, these different symptoms being more or less complete according to the variability of the fracture. The clinical diagnosis is ordinarily easy but nevertheless radiography should always be resorted to. In the majority of cases the prognosis is good, complications being relatively rare. When there is no displacement of the fragments or if the case is one of simple fissure fracture, recovery is prompt, while if there is displacement the ultimate outcome will usually be good. But the possibility of complications must not be overlooked. Besides, it is usually the right hand that is involved, so that its importance is manifest. Bennet estimates that loss of function lasts for several months; this is merely a mean, because published statistics show very variable results in this respect. Dorny states that in favorable cases the functions of the thumb are recovered in about five weeks from the beginning of treatment. However, there are cases, especially those that have been neglected, in which the complete functional recovery in the case of the thumb takes a much longer time. In the case of simple fracture, it is generally conceded that the mean time for consolidation to take place is from twenty to thirty days and that the average time of temporary incapacity is from two to three months. As to the diminution of the work ing capacity it varies according to the metacarpal bone involved. In the case of the second or third metacarpal bone the decrease of working capacity is estimated at 8.5 per cent. if the active hand is involved, and at 7 per cent. in the case of the passive member (Forgue and Jeanbrun). Espagnon refers to a case in which the courts at Nancy refused to order the payment of damages for simple stiffness or difficulty in flexion of the left ring-finger. It is very evident that the amount of damages to be exacted will vary according to the metacarpal bone or bones involved, as well as the hand and the profession of the injured person.

Diagnosis of Sex Through Measurements of the Atlas.

An important medicolegal and anthropological resource is described by Marcel Baudouin in *Le Progrès Médical* for June 5, 1920, xliii, 23. It has to do with the ratio between the length and breadth of the articular facet of the atlas which enters into the cranio-atlantoid articulation. The origin of the idea is an assertion or belief, that the sex in a skeleton may be told from the atlas, which has a folk lore basis and is found in some of the older anatomies. The statement goes back to classical times, for Catullus noted that the neck of a young girl was smaller than that of a boy of the same age. This refers to the muscular mass, but the latter varies directly with the size of the articulating surfaces, so that the lateral masses of the atlas are larger in man than in woman. From this crude idea the author has been able as a result of many measurements to show that the ratio or index between the length and width of the arti-

cular facets exhibits notable sex differences, being considerably greater in woman. We may measure both the condyles on the occiput and the excavations on the atlas. These do not agree exactly for the condyloid index is somewhat greater than the glenoid index, although naturally this does not affect the sex ratio. In certain old Gallo-Roman skeletons the author was easily able to identify the male sex by the low condyloid and glenoid indexes which were respectively 42.85 and 46.15. In female skeletons of the same people the ratios would have been between 55 and 65 or even more. This simply means that in the male the articular facet is long and slender in comparison with that of the female, in whom it is relatively short and broad. Hence the quotient of length divided by width and multiplied by 100 will give a much larger figure for the female.

Saint Anthony's Fire.

THIS hypothetical medieval malady has received the attention of Durodié in an article which appears in the *Journal de Médecine de Bordeaux* for May 10, 1920, xci. 9. Of its severity there can be no question. It was recognized under a great variety of names, mostly characterized by the term "fire" in various connections. Among the synonyms were several which bear saints' names—St. Anthony's, St. Firmin's, St. Marcel's, one name of a country, Persian fire, and several more or less descriptive terms, such as "sacred fire," "infernal fire," etc. The most striking symptom was a spontaneous amputation of the feet after intolerable suffering. There is a record of twenty epidemics between the years 827 and 1347 or in other words about four to a century. The mortality while not comparable with that of plague years, was considerable. Thus in Aquitania in 1020 no less than 40,000 persons perished. A century later the malady spread over most of France and appears to have lingered in the Empire for a number of years. A hiatus then occurs for some centuries when there was a recrudescence, five epidemics occurring from 1630 to 1747. The affection seems to have shown a tendency to appear in severe winters with preceding wet summers and poor harvests. The preference in some cases of the months of the harvests suggests the possibility that the disease was chronic ergotism. The author's explanation of this historical malady shows a notable discrepancy from an older view which dates back before the late war and which was commented on at the time in medico-historical circles. The other theory saw in the "Persian fire" the disease anthrax which bears no relationship with ergotism.

Grancher's Disease.

UNDER the name of splenopneumonia, otherwise Grancher's disease, Salveti contributes an article in *La Pediatria* for May 15, 1920, xxviii, 10, with case report. The original description by Grancher was as follows: The patient is first seized with a chill which is followed by a dry cough. The left side is the one nearly always affected at the outset. There is absolute dulness on percussion with disappearance of vocal fremitus. The condition resembles pleurisy with effusion to such a degree that puncture alone will differentiate between the two. The pneumonia is of a very rare type while pleurisy with effusion is of course common. Differentiation from ordinary lobar pneumonia is much easier. Autopsy finds are few because the disease is rather benign, recovery being the rule. As the author's case ended fatally it possesses considerable value. The patient was aged 2 years, and death may have been in part due to hemorrhagic encephalitis. The pulmonary lesions were as follows: purulent bilateral bronchitis; massive total pneumonia of the left lung of the so-called desquamative type; subpleural abscess in the upper lobe; right pneumonia in the upper and middle lobes. The tubercle bacillus was absent and the offending germ was probably Fraenkel's pneumococcus. No clinical diagnosis seems to have been made, as in addition to pulmonary lesions there were intracranial manifestations and nephritis. Pleurisy was excluded by puncture. The case is by no means a clear cut one and the author at the close intimates that since it occurred during the influenzal pandemic it may have been an aberrant grippe. Encephalitis has not hitherto been seen as a complication in Grancher's disease.

News of the Week.

Canton Hospital Anniversary.—The Canton Hospital, founded in 1835, will celebrate its eighty-fifth anniversary this year. This is the oldest and one of the largest hospitals in the Orient, and is the first missionary hospital in the world still in existence. During its existence more than two million patients have been healed in the hospital and its dispensaries. In the past decade 120,000 dispensary and 20,000 in-patients were treated, and 14,000 operations performed upon in-patients. During 1919, 2,500 in-patients and 12,000 out-patients were cared for, and over 2,000 operations were performed upon in-patients.

All-American Health Conference.—The first of a series of regional health conferences authorized by the International Health Conference in Cannes is to be held in Washington, D. C., December 6-13. It will be devoted to a consideration of venereal diseases. The conference is being organized under the joint auspices of the United States Interdepartmental Social Hygiene Board, the United States Public Health Service, the American Red Cross, and the American Social Hygiene Association. Prominent health officers and sociologists from all parts of North and South America will attend. Professor William H. Welch of Johns Hopkins will serve as president.

Standardized Rat-Proof Houses.—Health officers from various States and the larger cities, at a conference in Galveston and Beaumont, Texas, to study bubonic plague and rat extermination, recommended to Surgeon-General Hugh S. Cumming that standard specifications for rat-proof buildings be drawn up by the United States Public Health Service. In accordance with the recommendation, plans for radical changes in the construction of business buildings, dwellings and wharves are being drawn up by the United States Public Health Service as part of a nation-wide campaign for rat extermination. These are to be

furnished to the different States and cities in order that they may be incorporated in the building codes throughout the country.

War Loss in Population.—According to the report of a statistical research conducted by the Society for Studying the Social Consequences of the War, of Copenhagen, ten European nations engaged in the war sustained a potential loss in population of 35,320,000 persons since 1914. Of this number 9,819,000 persons were killed in war; 5,301,000 deaths were due to augmentation of mortality, economic blockades and war epidemics; 20,200,000 fall in birth rate due to the mobilization of 56,000,000 men.

New Public Health Journals.—The *International Journal of Public Health*, the official scientific organ of the League of Red Cross Societies, made its first appearance in July, with complete editions in French, Italian, and Spanish. The journal is published and edited in the Department of Medical Information of the League at Geneva. Dr. Thomas R. Brown is editor, Dr. W. W. Francis, associate editor, and there are six assistant editors. The journal will appear every two months for the present.

Group Consultation Clinics.—The New York State Department of Health announces the successful conduct of the Group Consultation Clinics at Goshen, held on three days last week by 314 physicians. This clinic was established by the State Department of Health in conjunction with the State Department of Education, the State Hospital Commission, State Commission for Feebleminded, the State Charities' Aid Association and the American Red Cross, the object being to provide such modern medical facilities for the country doctor as would enable him to reach a correct diagnosis in difficult and obscure cases. The success of this clinic has been so great that similar clinics are planned for other sections of the State.

Extension of Work for Undernourished Children Suggested.—Dr. Royal S. Copeland, Health Commissioner of New York City, is so pleased with the work of the summer play schools, established primarily for the benefit of undernourished and backward children, that he will recommend an extension of the movement. Five such schools were operated during the summer, medical reports from which show that the nutrition grade of every child increased about 15 per cent., and that every child gained two pounds in weight.

The Menace of Typhus.—Dr. Harry Platz, who returned recently from Poland, where he made a study of conditions for the Joint Distribution Committee, will lay before the Government authorities a plan for raising $75,000,000, either by Congress or through private subscription, to send physicians and workers from the United States to join the representatives of other countries in fighting the world menace, typhus fever.

Smallpox on Another Liner.—The Italian liner *Dante Alighieri*, which arrived from Naples and Genoa recently, brought a case of smallpox among its 2,002 steerage passengers. The 400 first and second class passengers were vaccinated and the steerage passengers were sent to Hoffman's Island for observation.

"Still the Greatest Mother in the World."—Under this title the American Red Cross will inaugurate its fourth roll call November 11 to 25. Instead of the wounded soldier of the war-time "Greatest Mother" poster, the new poster shows a crippled child, an aged man and a distressed mother, the central figure, the Red Cross nurse, remains the same.

Free Dental Clinics.—The health service department of New York County Chapter of the American Red Cross has published a directory of dental clinics, showing that fifty-one dental clinics in New York City give their services free or at nominal charges. Eleven of these specialize in work for children.

Down With the Pacifier!—Pacifiers, not pacifists, are now under fire. The Passaic County (N. J.) Midwives' Association has dubbed this nursemaids' delight a habit forming drug, and has declared war upon it. The assembly at Trenton will be enlightened with regard to the evils of the pacifier, and will be importuned to pass a law to save the babies therefrom.

Prize for Article on Tuberculosis.—The *Indian Medical Record* announces a prize of £10 to be awarded to the best writer on "Tuberculosis. Its Etiology, Prophylaxis, and Treatment." The competition is open to all qualified medical men in service or in practice. Communications may be addressed to A. C. Bishard, Managing Editor *Indian Medical Record*, 2, Horokumer Tagore Sq., Corporation Street, Calcutta, India.

Dental Work Needed.—It has been stated by the headworker of the University Settlement, one of the United Neighborhood Houses of New York City, that more than 98 per cent of the children in this district have defective teeth. A free dental clinic is said to be the only remedy for this state of affairs, the parents of the children in the majority of cases, being unable to pay for dental services.

Two-Year Sleep Broken.—A woman who is said to have been asleep for two years in a county asylum in Wisconsin has regained consciousness. During the long period when she was "bound in another world" the woman was as helpless as a babe, having to be fed and cared for as if she had been an infant.

Dr. E. F. Hartung, County Physician in Kings County and practising physician of Brooklyn was severely beaten and robbed of $4,000 in cash and jewelry recently by a "patient" to whom he was summoned by a confederate.

Colonel F. F. Russell has resigned from the Medical Corps, U. S. Army, to assume charge of the Division of Public Health Laboratories of the International Health Board of the Rockefeller Foundation.

Medical Society Elections.—At a recent meeting of members of the Regular and Reserve Medical Corps of the Army who served during the World War, called in Birmingham, Ala., for the purpose of organizing the Medical Legion of the United States, the following officers were elected: *President*, Dr. William M. Jordan; *Vice-President*, Dr. Gaston W. Rogers; *Secretary*, Dr. Leo C. Wood.

The Chicago Radiological Association, organized August 5, elected the following officers: *President*, Dr. Alonzo C. Tenney; *Vice-Presidents*, Mr. A. M. Olson and Mr. J. H. Brothers; *Secretary*, Mr. J. W. Ross; *Treasurer*, Dr. John H. Carpenter.

Charitable Bequests.—By the will of Berthold Bendheim of New York City, who died August 23, the following bequests were made: To the Federation for the Support of Jewish Philanthropies and the Hebrew Orphan Asylum $2500 each, and $2000 each to the American Red Cross, Mount Sinai Hospital, Montefiore Home, the Hudson Guild, Felicia Fresh Air Fund Committee and the Madison House Society; $1000 each to the Crippled Children's East Side Free School and $500 each to Tuskegee Institute, Beth Israel Hospital, Society for the Improvement of the Condition of the Poor, and St. Mark's Hospital.

By the will of Mrs. Nellie C. Black, wife of the late John C. Black of Chicago, the residue of her estate, amounting to about $500,000, is left to the Children's Memorial Hospital, Chicago, which, after twenty years, will receive also the principal of a $250,000 trust fund.

Medical Society Meetings.—THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS will hold its thirty-third annual meeting at Atlantic City, September 20-22, under the presidency of Dr. George W. Crile of Cleveland, Ohio.

THE NEW YORK AND NEW ENGLAND ASSOCIATION OF RAILWAY SURGEONS will hold its thirtieth annual session in New York City, October 19, under the presidency of Dr. William B. Coley.

THE AMERICAN PUBLIC HEALTH ASSOCIATION will hold its annual meeting at San Francisco, September 13 to 17, inclusive.

THE MEDICAL SOCIETY OF THE MISSOURI VALLEY will hold its annual meeting at Omaha, Neb., September 6-7, under the presidency of Dr. Charles Ryan of Des Moines, Iowa.

THE NATIONAL DENTAL ASSOCIATION held its twenty-fourth annual session in Boston, August 23-27. This meeting marks the sixty-second anniversary celebration of organized dentistry.

Obituary Notes.—Dr WILLIAM STEED FLORENCE, interne at Bellevue Hospital, New York City, died August 22. He was graduated from the College of Physicians and Surgeons in June of this year.

Dr. WILLIAM DE FORREST VOORHEES, formerly of Brooklyn, N. Y., died at Auburn, N. Y., August 28.

Dr. EDGAR ABBOTT of Boston, a member of the staff of the Massachusetts General Hospital, was killed in an automobile accident on August 30.

Correspondence.

DESCRIPTIVE PSYCHOLOGY AND MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Will you permit me to add something, in the way of comment and exhortation, to my article on Psychology and Medicine published in the MEDICAL RECORD of August 28. In that article I told something about the old psychology; and while the ancient science may not help the sick, it is essential to an understanding of the mental functions, just as anatomy helps to an understanding of physiology.

I also gave some indication of what the "new" psychology means and of what it aims to do. I feel very seriously that the medical profession, educators, and moralists ought to understand with what we are confronted in connection with this movement. This "new" psychology presents a one-sided, but definite method of dealing with the education and character-building of the young, and with human conduct generally. Its cultural technique involves a special ethics, a philosophy of life, and a means of treating mental abnormality and disease.

So the medical profession, and especially those interested in public health and mental hygiene, ought to take a definite and carefully studied stand as to the sanity and wisdom of applying psychoanalysis in the moral, mental, and physical education of adolescents and others. Adopting it, we will bring up our children and direct our own lives on the theory that our motives, our conduct, and character are determined by certain highly organized subconscious activities largely sexual and infantile. The young will be shown that by a close and meticulous study of their early experiences and dreams they will learn to know themselves and adjust their conduct and their ideals accordingly. They will learn that man is under the control of these particular psychic laws, and can only make himself what such laws allow. Is this going to be the main and preferable method of developing mind and character? I hold that it is not, though I believe that psychoanalysis has a field and I respect highly those who are following in it intelligently and conscientiously.

Probing into the past life, and rooting up complexes, showing the real psychic causes of morbid habits of thought ought to be of help to some who have grown up with wrong points of view, and who do not know that they have removable maladjustments. This conception or new psychology gives us a technique for carrying out the old Socratic advice "know thyself." But I also hold that it is a dangerous therapeutic and pedagogic tool and one of limited value. It cannot take the place of methods of training and treatment approved by experience; nor, perhaps, of the Sermon on the Mount or any equivalent appeal. I would place it in therapeutics along with physical training, dietetic teaching, narcotics and bromides as one of the handmaids of medicine serving only a wise master.

After all, the really new psychology is not dynamic or behavioristic, or descriptive or somatic, but it will include all methods of observing and interpreting the psychic functions of the brain and explain the fundamental causes of human conduct. This is the modern, ultimate eclectic psychology.

CHAS. L. DANA, M.D.

THE LATE DR. LAASÉ AND THE DRUG LAWS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I would like to ask the privilege of qualifying a statement prominently published in a New York newspaper in which the late Dr. Christian F. J. Laasé of this city is referred to as a "Foe of Drug Laws." It is felt that this characterization may reflect somewhat upon the reputation of this lamented laborer in the field in which he was beginning to achieve distinction, the study and treatment of the disease of narcotic drug addiction.

Dr. Laasé's opposition to drug laws was confined to combating these measures while they were up for legislative action, notably in this state, the last instance being the Cotillo Drug bill, which was repealed by the New York legislature as drawn in the interest of the compulsory institutionalization of drug addicts. That he obeyed these laws when enacted as far as it was humanly possible to do so was proved by his acquittal in the Federal Courts, where it was shown to the satisfaction of a jury that he had acted in good faith in all his dealings with his patients both as a physician and as a law-abiding citizen.

The Harrison drug law is now opposed by those whose activities in drug legislation in this state was looked upon by Dr. Laasé as inimical to the welfare of the victims of drug addiction and of the rights of the practitioners of medicine on the other hand. The term "foe of drug laws" may now be justly applied to them as they are responsible for a statement recently sent broadcast throughout the country in the form of an interview with Dr. Frederick R. Green, secretary to the Council of Health and Public Instruction of the American Medical Association.

This report elaborates and intensifies the objections to the Harrison law embodied in the one originally made by the Council of Health and Public Instruction and printed as follows in the Journal of the American Medical Association: "The Harrison law has now been in operation a sufficient length of time to afford a fair opportunity for determining its effectiveness. It must be admitted that it has failed of the purpose for which it was enacted, viz., the restriction of the use of habit-forming drugs to legitimate purposes. Reports indicate that efforts to enforce the law in the face of this over supply of drugs have resulted in the marked increase in the illicit distribution of opium, morphine, heroine, cocaine, and other inhibited drugs, while the extortion of unfortunate victims of drug habits have been made possible by the illegal methods under which the traffic is necessarily carried on. Reference is also made to the fact that 'the opportunities for profit due to the dishonest enforcement of the law in different localities has led to blackmail and official corruption." The remedy offered is the control by the United States Public Health Service of the control and distribution of habit-forming drugs. Although the compulsory institutionalization of drug addicts by this body is not mentioned, its contemplation may be surmised by the condemnation of the ambulatory treatment of drug addiction by the American Medical Association at the time this report was adopted. Nothing is said in this report about the dangers attaching to the prescribing for addicts by reputable physicians under the rulings of the Department of Internal revenue at the present time. By reason of this danger physicians everywhere have refused to treat these sufferers. This is the real reason for the growth of the illicit trade, the blackmail, and the extortion in connection with the law and now condemned by the American Medical Association.

JOHN P. DAVIN, M.D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 6, 1920.

First Annual Meeting of the Federation of Medical and Allied Societies.—Sir Malcolm Morris presided over the first annual general meeting of the Federation, which was held in London on July 25 last. After the report of the executive council had been read, Sir Malcolm Morris gave his presidential address and said in part that the need for such a Federation could be deduced only too easily from the experience of the last few years. Was it possible to maintain that when questions affecting the welfare of the great body of medical men had been before Parliament the profession had been able to pull its full weight? Was it so, for example, when the health insurance system was being framed? Certainly it was not. Who that cared supremely for the highest interests of the profession—and among these highest interests he ranked its good repute—could look back upon the stormy events of those days without some sense of humiliation? The chaffering in public into which the profession was forced was only too well calculated to give the impression that medical men were thinking very much of their material interests and very little of the nation's welfare. Had there been in existence such a body as the Federation was fast growing to be, how different would have been the beginnings of health insurance. The Government would have known at the outset that it had to reckon with a Federation through which were able to speak not only the doctors, but also pharmaceutical chemists, who were immediately concerned, and related bodies which had no material interests at stake to deflect their judgment. How could the deliberate conclusions of such a Federation have failed to carry weight with the Government, and with that public opinion which was the final court of appeal? The need for federation was deducible not less plainly from the multiplicity of existing organizations. That there were some 200 separate medical bodies certainly showed that the profession was not lacking in the organizing faculty. But was it not evident that the effect of all this organizing energy would be vastly strengthened if these bodies were leagued together? They were influential in very different degrees. But were they all federated, the most powerful would have their influence increased tenfold; the least powerful would have their influence increased a hundredfold. With regard to politics, the speaker said that it could not be too often insisted upon that the Federation knew no party politics. To say that it knew no politics would be absurd, for the most important of its objects was to take political action at every possible opportunity. But it gave its support, its active and influential support, to Lieutenant-Colonel F. E. Freemantle, who was elected as Coalition Unionist, and to another member of the profession, Dr. Dunstan, who stood as a Labor candidate. And every medical member but one of the legislature except Dr. Addison, whose office debarred him from formal association with a movement with which he had none the less avowed his

sympathy, including Lord Dawson, who could speak for the profession in the House of Lords, belonged to the Federation. The medical members of the House of Commons now numbered ten, and it was known that they were only the advance guard. Before long, with the active backing of the Federation, their numbers would be multiplied, and the time was at hand when, on all questions affecting health interests, the Whips would have to reckon with a solid phalanx of medical men who would be able to speak with one voice on public health, however much they might differ on other questions. If any Government starved the Public Health Service they must cry "Hands off," and a powerful medical group in the House of Commons would be a bulwark. Behind it would stand the Federation. No longer would it be a "grave defect in medical organization," to use Dr. Addison's words, that there should be "no body of men in the profession who could be appealed to for judgment on a great public issue." Such a body the Federation was destined to become. That the system known as State medicine would undergo much further development was inevitable. The profession had no alternative but to adapt itself to the nation's needs, whatever form the adaptation might take. That task would require more statesmanship than was to be found in any one of the existing medical organizations, be it never so powerful. It was an enterprise which would tax to the uttermost the statesmanship of the whole profession. If that were so, how could any medical society or association be justified in withholding whatever contributions it could make to the common stock?

It would seem that the medical profession of Great Britain has finally realized the necessity for thorough organization. In fact, it has become a question of self-defense. The allied societies of the country are splendidly organized, and unless the medical men are strong enough to resist them, these societies will simply dictate terms to them. As Sir Malcolm Morris truly said, the Health Insurance Bill should open the eyes of medical men to what is before them unless they are in a position to fight for their rights. At present they are almost politically impotent and to a great extent at the mercy of self-seeking, self-serving politicians who are more than ever firmly convinced that vox populi is indeed vox dei. Of course, it is obvious that the character of medical practice is changing and that it is useless for doctors to kick against the pricks. They must adapt themselves to circumstances so long as these are not wholly opposed to the dignity of the profession and their interests. They must give and take, but must not allow themselves to be merely so many pawns in a bureaucratic system and in which public and individual health play but subsidiary parts. The only way in which the profession can assert itself is by union and organization. It only requires political power to protect itself and to lead in health matters rather than to be led or driven by those whose object is not so much the conservation of health as the consummation of their own political ambitions.

Congress of the International Society of Surgery.—Dr. W. W. Keen of Philadelphia presided over the fifth congress of the International Society of Surgery, which took place in Paris, July 19-23. It will be in the recollection of our readers that the fourth congress of this society was held in New York in April, 1914. It will be also remembered that at this meeting Dr. Depage was one of the most prominent figures, and that he was accompanied by his charming wife, Madame Depage, who was drowned in the Lusitania murder. At a preliminary meeting held just before the opening of the congress it was determined that Germans, Austrians and Turks should be excluded from membership. Hospitals and clinics were visited each morning of the week during which the meeting was held, and on every afternoon there was a scientific meeting. The opening session took place on the afternoon of July 19, when an address was given by Mr. Honnorat, the Minister of Education. Professor Keen, in his inaugural speech, took as his subject "Some of the Ideas Which as Doctors We Ought to Defend." He dealt with many questions of medical concern including those of the education of the medical man, scientific research, professional conscience, venereal disease, the altruism of the medical profession, and the value of total abstinence. Dr. E. A. Graham of New Orleans read a paper on asphyxia, in which he pointed out that this condition might be produced by (1) interference with the intake of air; (2) interference with the power of the blood to carry oxygen or to remove carbon dioxide; (3) interference with the circulation of the blood; (4) disturbance of the power of the tissues to utilize oxygen. He showed that a change of pressure in one pleural cavity is associated with a similar change in that of the opposite side. Both lungs, therefore, were nearly equally compressed when their expansion was restricted by air or fluid. The commonly accepted condition of "collapse" of one lung with maintenance of respiration by the other did not occur.

In the section of radiography over which Sir D'Arcy Power presided Dr. Abbe of New York gave a lantern-slide demonstration of the beta and gamma rays, and demonstrated the effects of magnetism upon the radium emanations. Dr. Coolidge showed his apparatus for taking *x*-ray pictures.

The next meeting will be held in England in 1923 under the presidency of Sir William Macewen, Mr. Charles Ryall becoming a delegate. It was decided that the subjects for set discussion in 1923 should be: (1) Serotherapy and vaccinotherapy in surgical affections. (2) Fractures of the base of the skull. (3) Malignant disease of the colon. (4) Arthroplasty. The public banquet was held at the Palais D'Orsay and was attended by more than 150 ladies and gentlemen under the chairmanship of Professor Keen.

Oxford Ophthalmological Congress.—The eleventh annual meeting of this congress was held in the department of anatomy, Oxford, July 14-16 last. On the first day a discussion on Perimetric Methods was opened by Dr. Luther C. Peter of Philadelphia, who dealt with the newer methods of perimetry and the type of cases for which they were especially adapted. He drew attention to the inefficiency of the ordinary perimeter in re-

cording changes in the central zone and discussed the various modern instruments best adapted for this purpose. The speaker suggested a change in the nomenclature from linear measure in millimeters to angle subtended in degrees or minutes, and discussed the size of the test object, for color studies in particular. The size for the central zone should subtend an angle of half a degree and that for the peripheral zone one degree. The special methods required for the study of bilateral central scotomata were (a) by making use of muscle sense, and (b) by the method of Dr. Peter for combining perimeter and campimeter.

Obituary.—Dr. James Scarth Spence Logie died at Kirkwall, Orkney, on July 17 last, in the 101st year of his age. He qualified L.R.C.S. Edin., in 1841, and practised during the greater part of his working life in Kirkwall, his practice extending over the whole of Orkney. There being no roads nor wheeled vehicles in the island when he began practice his professional visits were perforce made on horseback over rough hill country or in small sailing boats. Dr. Logie was medical officer of health for Kirkland. He was 100 years old on May 1 last, when he received letters and telegrams from the King, the Senate of Edinburgh University, and from the General Assembly of the Church of Scotland, of which he had been ordained an elder in 1855.

1. Acidosis of the Recurrent Vomiting Type. The Case of Darthea M. W. W. McKibben.
2. Preventive Medicine as Applied to the Individual. J. P. Bill.
3. The Question of Drainage in Cholecystectomy. John T. Bottomley.

1. Acidosis of the Recurrent Vomiting Type.—W. W. McKibben reports in detail the case of a child twenty months old whose history is illustrative of the type of acidosis known as recurrent, cyclic or periodic vomiting. Babies and children of neurotic ancestry, he says, and of lithemic diathesis tend to periodic attacks of vomiting. This is due to disordered fat and carbohydrate metabolism, as well as to sensitization to certain definite food proteins to be found out by skin reactions, or even more important, by experimentation with the foods themselves. The best way to meet the attacks is by stopping everything by mouth and giving one or two cleansing irrigations daily of sodium bicarbonate; and glucose or dextrose in solution by rectum; for the interval, elimination from the diet of all proteins to which the baby is sensitive until the baby desensitizes itself, or is desensitized; also a low fat and sugar intake. It is essential when nearing the cycle, or when the slightest symptoms recur, to watch, or better still, to have the urine closely watched by a physiochemist, so that at the first warning, a sufficient quantity of sodium bicarbonate may be given to neutralize the urine or to render it alkaline. It is important that these precocious children have long hours of sleep, and play alone out of doors as much as possible.

1. A Word to the General Practitioner About the Handling of Eye Cases. Edwin B. Miller.
2. Report of Five Operative Eye Cases. Edwin B. Miller.
3. Eye Conditions of Interest to the General Practitioner. Louis F. Love.
4. The History of Acidosis. William Henry Donnelly.
5. Report of a Case of Melanoma. S. R. Monteith.
6. Nephritis. Hyman I. Goldstein.
7. Child Health Work in the Solvay School. George M. Retan.

3. Eye Conditions of Interest to the General Practitioner.—Louis F. Love aims, in this paper, to give to the busy physician, in succinct form, the information he may require in his work, and to aid him in treating intelligently eye conditions that too often are neglected because of insufficient knowledge of the subject, particularly that pertaining to the differential diagnosis of the commoner eye affections. The diseases which he discusses as coming under this category are conjunctivitis; ophthalmia neonatorum; keratitis eczematosa, phlyctenular keratitis, or phlyctenular conjunctivitis; iritis; glaucoma.

7. Child Health Work in Solvay Schools.—George M. Retan discusses the health work conducted in the schools of Solvay, an incorporated village of 6,000 population, a suburb of the city of Syracuse. The objects sought were the lowering of the mortality rate, the prevention of sickness, and the encouraging of the best possible mental and physical development in each individual child. The work is divided into four general heads: 1. the prenatal clinic; 2. the infant welfare clinic; 3. the preschool clinic which fills the gap between the age of infancy and the school age, and 4. the school welfare work which takes the child from kindergarten through high school. The entire work is under the supervision of the school physician. The staff consists of the school physician, an ophthalmologist, a dentist, a dental assistant, two school nurses, one baby welfare nurse, a visiting housekeeper, a nutrition worker, and a physician who conducts the prenatal clinic. None of the work described, according to the writer, costs too much for any community if it is expected to train a generation of virile, healthy, energetic men and women.

Journal of the American Medical Association.

1. Studies in Basal Metabolism. A. M. Snell, Frances Ford, and L. G. Rowntree.
2. The Causes of Emotivity, and Their Management. Tom A. Williams.
3. Endocrine Imbalance in the Feebleminded. Oscar J. Raeder.
4. The Surgical Treatment of Brain Abscess. A. W. Adson.
5. Correction of Congenital Clubfoot in Infants. Isadore Zadek.

1. Studies in Basal Metabolism.—Snell, Ford and Rowntree, in this study, which is accompanied with illustrations, charts and tables, give the results of an experience extending over fourteen months and involving approximately 750 determinations on 350 persons. They give detailed consideration to basal metabolism in certain diseases of the endocrine system. Hyperthyroidism, febrile diseases and leukemia exhibited the highest rates, while hypothyroidism, polyglandular deficiencies and afebrile conditions resulting from inanition and marked asthenia yielded the lowest rates. Starvation and prolonged rest in bed tend to result in low rates. From this extensive study the following conclusions are formulated: 1. The gasometric method of indirect calorimetry is a reliable and practical clinical method for determining the basal metabolic rate. 2. The basal metabolic rate is of the greatest significance in diseases of the endocrine system, particularly in diseases of the thyroid, revealing the extent of the increase in metabolism in exophthalmic goiter and in thyrotoxic adenoma, and the extent of the decrease in metabolism in cretinism and myxedema and allied conditions. 3. The basal metabolic rate furnishes an accurate index to the results of medical and surgical treatment of these conditions, and thereby becomes of value as a guide to treatment. 4. The basal metabolic rate is of value in revealing the effect of drugs on metabolism.

4. The Surgical Treatment of Brain Abscess.—A. W. Adson. See MEDICAL RECORD, May 29, p. 934.

5. Correction of Congenital Clubfoot in Infants.—Isadore Zadek holds that the treatment of congenital clubfoot should be begun early. It should be continued until the dorsum of the foot rests easily against the lower end of the leg, and this position should be maintained for about two months, if there is no tendency to recurrence, as in the average case. In the usual run of cases no brace is indicated. Too much reliance is placed in the use of clubfoot braces. The conventional brace is only retentive and not corrective. Frequent daily manipulations, opposite the original deformity, are essential until the correction is assured.

1. An address on Toxic Idiopathies: The Relationship Between Hay and Other Pollen Fevers, Animal Asthmas, Food Idiosyncrasies, Bronchial and Spasmodic Asthmas, Etc. J. Freeman.
2. The Croonian Lectures on the Psychology of the Special Senses and Their Functional Disorders. Arthur F. Hurst.
3. Symptomless Influenzal (Streptococcal) Mastoiditis. Francis F. Muecke and C. Grantham-Hill.
4. The Classification of Pulmonary Tuberculosis. L. S. Burrell.
5. Sulfarsenol in the Treatment of Syphilis, with Special Reference to Its Administration by Hypodermic Injections. F. Carminow Doble.
6. Pleural Obliteration; a Complication of Artificial Pneumothorax. W. C. Rivers.
7. Vertigo: Its Relation to Errors of Refraction. C. Ernest Pronger.

1. An Address on Toxic Idiopathies.—J. Freeman holds that the apparently diverse affections which he designates by the group name "toxic idiopathies," and which include hay fever, other pollen fevers, animal asthmas, food idiosyncrasies, bronchial and spasmodic asthma and sensitiveness to foreign proteids (worms, insect bites), are linked together in an extraordinary way by (1) their selectiveness; (2) by the symptom complexes; and (3) by heredity. The connecting link, if only one could discover it, must have great significance in immunology; the detection of one definite toxic idiopathy in a patient should put one on the alert to discover others; and anything that is learned about one will help in dealing with another toxic idiopathy. This refers chiefly to treatment. Excluding all the palliatives, one has the choice of two treatments for all of them—(1) avoiding the particular irritant, or (2) immunizing against it. The study of these toxic idiopathies, in the writer's opinion, will open a new field of medicine, but they throw light from a new angle across a very large field of the old medicine.

4. The Classification of Pulmonary Tuberculosis.—L. S. Burrell proposes the following classification of pulmonary tuberculosis, from which doubtful cases are excluded: The first stage, A, is subdivided into (1) the hospital stage, and (2) the sanitarium stage. Stage 3 is the stage of decline, and includes patients who are losing ground in spite of treatment. These stages are subdivided as follows: A. *State of institutional treatment.*—1. *Hospital stage.* a. In bed, or up less than two hours a day. b. Up from two to six hours a day. 2. *Sanatorium stage.*—a. Capable of less than half a day's work. b. Capable of half a day's work. c. Capable of a full day's work. B. *Stage of maximum improvement.*—1. Capable of a full day's work. 2. Capable of part-time work. 3. Unable to work. C. *Period of decline.* 1. Able to do some work. 2. Unable to work. 3 Bedridden.

The British Medical Journal.

July 31, 1920, ii, 3109.

1. The Present Position of Vitamines in Clinical Medicine. Opening papers by Professor F. Gowland Hopkins and Sir James Barr.
2. The Treatment of Calculi Impacted in the Pelvic Portion of the Ureter. Frank Kidd.

1. The Present Position of Vitamines in Clinical Medicine.—F. Gowland Hopkins, in opening this discussion before the Section of Medicine of the British Medical Association at its Eighty-Eighth Annual Meeting, said the modern conception of a deficiency disease is not based wholly upon a belief in the existence of vitamines. There may be quite other factors of deficiency in a diet which may produce symptoms to be observed clinically; but the hypothesis of vitamine deficiency plays a large part in current views concerning the chief examples of the conditions which he discusses (scurvy, beri-beri, xerophthalmia, rickets). The term vitamine "hypothesis" is eschewed by the writer. Vitamines, though still of unknown nature in the chemical sense, are not merely hypothetical. Those who believe in vitamines will doubtless be in a stronger position when the chemical nature of these substances is known, and when they can be administered in a pure condition. Short of that, however, the existence of these accessory factors in nutrition—factors which one can already sufficiently define—is now sure, and needs no further evidence. In connection with the clinical evidence one can seldom expect such clear-cut manifestations as are seen in experiments where only one factor is varied and all others controlled. In practice there will be, for instance, only very occasionally, complete absence of any one factor from the diet. Usually the deficiency will be partial only, and often this partial deficiency may involve more than one factor. It is most important to remember that the absence of a specific factor from the food produces results very different from those that follow actual starvation. In the latter case the energy requirements and other demands are met from the tissues, and there is rigid economy of effort and material. Some harmony, too, among all the processes is secured. But when an individual's diet is deficient in, say, a vitamine, he may still be dealing with large quantities of total food. The metabolic machinery may be working at full pressure while neverthless deprived of some essential wheel or cog. Another aspect of these same relations is illustrated in the experimental fact that the necessary vitamine supply is quantitatively not independent of the amount of diet as a whole, nor even of its character. Many possibilities will here occur to the mind of those accustomed to think in terms of metabolism.

Sir James Barr, while realizing that for anyone in the present day to deliberately say that he does not believe in "vitamines" is tantamount to pronouncing his own anathema maranatha, approaches the subject in a skeptical frame of mind. He believes in accessory food factors, substances which are essential to nutrition and even to life itself, though they have no intrinsic food value of their own. The chemical constitution and physiological effects of such substances are well known, whereas "vitamines," so far as their composition is concerned, seem to be a figment of the imagination. He develops the subject along this line.

2. The Treatment of Calculi Impacted in the Pelvic Portion of the Ureter.—Frank Kidd lays down the following golden rules: Be careful not to mistake the shadow for the substance. Always give Nature a chance and do not be in a hurry to perform a major operation. Train yourselves to employ minor surgical methods, which is the line of safetly for the patient.

2. Bacillary Dysentery in Children.—Wilburt C. Davison calls attention to the fact that bacillary dysentery in infants sometimes masquerades under the names of summer diarrhea, infectious diarrhea, colitis or ileocolitis, which do not have the prestige and importance that is attached to the more ominous title "dysentery." That this disease in children is caused by *B. dysenteriæ* has long been known, and is adequately confirmed by the bacteriological findings in the 134 cases of diarrhea on which this study is based. Of these 134 cases of diarrhea, 71 were diagnosed by the clinicians as cases of dysentery (ileocolitis). Clinically, the disease is a definite type, occurring usually in well nourished and previously healthy children whose ages ranged from 3 months to 11 years. The ages of the 45 patients in the private practices of several physicians in Birmingham, Alabama, were higher than those of Baltimore. This may possibly be explained by the fact that in the former breast feeding was a more general rule and therefore the younger children escaped infection. With one or two doubtful exceptions, none of the patients was exclusively breast fed, but received supplementary feedings of whole milk, proprietary foods or general diet. The onset was usually characteristic and sudden. The child lost its appetite and showed evidence of having fever. Irritability, vomiting and convulsions were frequent initial symptoms. Within a few hours there was an increase in the number of stools. These were at

first fecal, rarely green, becoming blood-tinged on the second day, and within four days consisted almost entirely of blood and mucus. The number of stools ranged from 3 to 30 a day. The size of the stool was usually small and seemingly out of proportion to the patient's efforts. The fever subsided in most cases by the fifth day. The patients were usually quite ill, crying feebly when disturbed, were drowsy and apathetic, after their initial irritability had ceased, and had little or no appetite. Loss of sleep due to frequent and painful bowel movements was a distressing factor. Dehydration and marked loss of weight was evident by the end of the first week. In the patients that recovered, the blood disappeared from the stools during the second week and the diarrhea abated by the fourteenth day. Such was the course in 79 per cent of the cases. In 14 per cent (4 cases), however, the picture was misleading. In the dysentery cases in Baltimore and Birmingham there were 67 white children with 14 deaths and 4 colored with 1 death, a total mortality of 21 per cent. From the study of these cases Davison formulates the following conclusions: 1. Over 80 per cent of the acute cases of ileocolitis both in Baltimore and Birmingham were due to infection with *B. dysenteriæ*. 2. *B. dysenteriæ* (Flexner) is more prevalent than *B. dysenteriæ* (Shiga) in Baltimore, Maryland, and Birmingham, Alabama. 3. Clinically as well as bacteriologically the Baltimore and Birmingham cases were identical. 4. *B. dysenteriæ* (either Flexner or Shiga) was not found in the stools of 63 cases of simple diarrhea nor in those of 100 normal children. 5. The name ileocolitis should be changed to dysentery in children and the disease made reportable to the health authorities. 6. Dysentery (ileocolitis) is probably spread from the stools of one patient to the food and mouths of other children by flies and infected hands and not disseminated from a general dairy source. 7. Dysentery is less prevalent among children receiving breast milk or boiled milk mixtures in boiled containers. 8. The agglutination reactions of the patient's serum by standardized technique is of assistance in the diagnosis of dysentery. 9. *B. Morgan No. 1, B. welchii, B. pyocyaneus, B. proteus,* and the *Streptococcus fecalis* are not the cause of dysentery (ileocolitis) or diarrhea.

4. An Experimental and Clinical Therapeutic Study of Whooping-Cough.—David I. Macht made a study of about 115 cases of whooping-cough, the majority being children ranging in ages from a few weeks to fourteen years. All other medication was discontinued and the patients were given a 20 per cent. solution of benzyl-benzoate by mouth. The dosage varied from 5 to 40 drops in water, three or four times a day and oftener, depending upon the age of the patient and the severity of the disease. If the simple alcoholic solution of benzyl-benzoate was found to be too distasteful to the young patients it was flavored with a few drops of benzaldehyde and the medicine was administered in sugar water or milk. About 90 per cent. of all the patients showed more or less beneficial effects; about 50 per cent. exhibited marked improvement in the symptoms. The therapeutic effects of benzyl-benzoate were not of a curative character but were of a distinctly palliative nature. The findings are summarized in the following conclusions: 1. The administration of benzyl-benzoate solution alone and still better, in combination with small doses of benzaldehyde, exerts a beneficial palliative effect on the violence and number of whooping-cough paroxysms. 2. The mode of action of the drug in such cases has been investigated experimentally (discussed by the writer in the text). 3. In view of the low toxicity of benzyl-benzoate and benzaldehyde, and the considerable number of successful therapeutic results obtained with them, their further trial in the symptomatic treatment of paroxysmal cough and especially of whooping-cough is deemed advisable.

La Presse Médicale.

Thymus Death.—Pulawski describes a case of so-called thymus death in a youth of 18 who was under treatment for epilepsy in a Warsaw hospital. He was forbidden to bathe alone but disregarded the command and was found dead in the tub clad in shirt and drawers. It was evident that he had attempted only a footbath from the state of the underdrawers which were rolled up. While thus occupied he had had a fit and had fallen in the tub which was a third full of water and there and then had drowned? The alternative includes death before drowning could have occurred. Death during a crisis of epilepsy is extremely rare. Autopsy now showed no evidence of death by submersion for the lungs and stomach were alike empty of water. On the other hand there were evidencs of edema of the lungs, but asphyxia should have been accompanied by a distended right heart while these cavities were found quite empty. The subject presented an enlarged and persistent thymus and the other phenomena of the status thymicolymphaticus. Ever since the time of Felix Plater it has been known that enlarged thymus stands in some relation to sudden death and the number of recorded cases of this coincidence is now very large. Although this coincidence is recognized in the explanations of sudden death we still know nothing of the mechanism. In 1830 Kopp stated that compression of the inferior laryngeal nerve by the mass caused death by induced spasm of the glottis. This theory was upset by Friedleben in 1858. Not until about 30 years later did Paltauf isolate the lymphatic constitution and its relation to sudden death from cardiac paralysis. Next the endocrine theory asserted itself and the excess or diminution of some hormone was invoked to explain these deaths. Later it has been claimed that in new born children the old mechanical factor of Kopp might obtain and sufficient tracheal compression result to cause sudden death. This explanation however has no application to adult life and the problem here is still unsolved.

La Riforma Medica.

May 1, 1920, xxxvi, 18.

Lethargic Encephalitis.—Gasbarrini and da Gradi have made elaborate clinical studies of this affection as follows: Urine: In nineteen patients this was subjected to numerous special tests. Both retention and incontinence were seen in lethargy, but no constant phenomena were seen. Incontinence was present in three fatal cases and retention in three others, of whom two recovered. There was never any positive diazoreaction, nor sugar, nor acidosis. Adrenaline glycosuria was obtained once in a subject with Graves's disease. Indican was constantly present, while the elimination of urea and uric acid was practically unchanged. About half the patients had albuminuria and in three fatal cases albumin was associated with casts. Research in twelve cases for adrenaline mydriasis gave nine positive results. Blood tests: As a rule there was leucocytosis, but in a few cases leucopenia. In seven cases the red cell count and hemoglobin were normal. Vital staining showed in most cases lessened number of red cells and anemia was the rule during convalescence. Cerebrospinal fluid: Nothing new was learned here, the finds showing much inconstancy. Thus in sixteen cases tested there was a lymphocytosis in ten, while in the balance the find was normal. Ultramicroscopic examination of various secretions and nervous substance was always negative. One patient in fifteen tested gave a positive Wassermann and negative results with typhoid, paratyphoid, Weil-Felix, and other diagnostic reactions were all negative, save one positive typhoid, which stood in some relation with recent immunization. Hemoculture: Negative throughout. Experimental injections of blood in man and animals: These were negative save a few quasi-positive results in guinea pigs. Cutireactions: Certain vaccines were tested in this manner, including a Pfefferian culture. The latter experiment was of special interest and certain positive results obtained were difficult of explanation. Further study along this line may prove instructive.

Cerebral Softening Simulating Lethargic Encephalitis.—Baudoin and Lantuejoul have seen a patient who presented the classical triad of sleeping sickness—somnolence, fever and ocular pareses. On the seventh day of these symptoms death occurred and autopsy showed a vast focus of softening. The spinal fluid contained 256 lymphocytes to the cm., consisting almost entirely of intact polynuclears.—*Gazette des Hôpitaux.*

Book Reviews.

PSYCHOANALYSIS. A brief account of the Freudian Theory by BARBARA LOW, B.A., Member of the British Psycho-Analytical Society, formerly Training College Lecturer. Introduction by ERNEST JONES, M.D., M.R.C.P. (Lond.) President of the British Psycho-Analytical Society, Editor of the "International Journal of Medical Psycho-Analysis"; Author of "Papers on Psycho-Analysis." New York: Harcourt, Brace and Howe, 1920.

IT is the fashion to allude nonchalantly to psychoanalysis, on the stage, over the tea cups, in the pages of magazines, we hear of Freud, of complexes, repressed desires, and so for the dilettante of knowledge, who wishes to take his part in pseudo-scientific repartee we can recommend this book. In less than 200 small pages Miss Low has presented a quite acceptable résume of the pure Freudian School. It is hardly a work for the physician, however, except possibly as a preliminary to a more comprehensive work, such as Freud's own, or Pfister's. The value too of a book of this sort to a neurotic or other candidate for psychoanalysis is extremely problematical; most psychoanalysts undoubtedly would prefer their patients to be enlightened by themselves. These shortcomings are inherent, however, in the scope of the book, not in the book itself, which is very well done.

THE MEDICAL CLINICS OF NORTH AMERICA. Volume 3. Number 6. Chicago Number. May, 1920. Published Bi-Monthly by W. B. Saunders Company, Philadelphia and London.

THIS number contains the contributions from the clinics of fifteen teachers of medicine in Chicago. In all over twenty topics are presented. The material is interesting and instructive and well presented. The character of the volume as a whole is about the same as that of its predecessors in this series.

PRACTICAL ORGANOTHERAPY; the Internal Secretions in General Practice. By HENRY R. HARROWER, M.D., F.R.S.M. (Lond.). Glendale, Cal.: The Harrower Laboratory, 1920.

THIS book of 270 pages is written by one who is an acknowledged authority on endocrine therapy and it is a mine of information to the inquiring physician anxious to learn something of the how and why of indocrinology. Especially would we recommend a perusal of Section II, which deals with "The Basis of Organotherapy" clearly and practically. The following sections are on "Practical Organotherapy," "The Diagnosis of the Internal Secretory Disorders," and "Everyday Organotherapy." The author has much to say on pluriglandular therapy and defends it with vigor against the attacks of the sceptical and ignorant who think they smash it with the potent phrase "shotgun prescription." The neurologists have much to say regarding pluriglandular disorders and there can be no doubt of the existence of such. The relation of this to pluriglandular therapy is evident to all but the closet therapeutists who probably couldn't tell a patient if they saw one. However, this is not the place for a discussion on endocrine therapy; for such the reader is referred to the articles appearing in great number in this and other medical journals, and especially to Dr. Harrower's little book.

THE EXTRA PHARMACOPŒIA. Revised by W. HARRISON MARTINDALE, Ph.D., Ph.C., F.C.S., and W. WYNN WESTCOTT, M.B. Lond., D.P.H. Seventeenth Edition. In Two Volumes. Vol. I. London: H. K. Lewis & Co., Ltd., 1920.

THE new edition of this veritable cyclopedia of materia medica and therapeutics will be warmly welcomed by the large and happily growing fraction of the medical profession that believes in the efficacy of drugs in the treatment of disease. It is five years since the sixteenth edition of the work appeared and since that time much material of great value has accumulated, waiting to be recorded in permanent shape. What this material, now incorporated in the book, is the authors set forth briefly in the preface. Not only has much that is new been added, but much that is old and obsolete has been excised. A curious instance of forehandedness in Germany, showing how that country had for years been preparing for fiendishness in the war which it was waiting for a fitting opportunity to declare, is given in the preface. For years a study of poison gases had been carried on by Lehmann and his pupils under the camouflage of industrial hygiene, the results being published from time to time in the *Archiv für Hygiene*. In the meanwhile nothing of the kind was done in Great Britain, the main reason being no doubt that the English never had a thought of resorting to such inhuman measures after having promised, with Germany, not to do so. A new feature is the description of the mode of manufacture of a large number of drugs formerly made in Germany, the English patents on which have now expired. There are many other good points, some new, some familiar to older students of the Extra Pharmacopœia. As has been the case since the beginning, each new edition is better than the one before it.

1104 PICTURED NOUNS IN ITALIAN, FRENCH AND SPANISH, WITH ENGLISH INDEX. By CLARENCE E. SWEZEY. New York. Published by the author, 1920.

ALTHOUGH this is not a medical book, it nevertheless might be found useful by a physician called on to treat immigrants who have been in this country too short a time to pick up sufficient English for their needs. The words pictured in the book are all nouns and so arranged that pictures and definitions can be referred to instantly. As an illustration: A child, say an Italian, has swallowed a pin; the frightened mother, knowing little English, tries to tell what has happened; the doctor is likewise ignorant of Italian, but he gives her a copy of the book, she sees the picture of a pin and points to it. She says *spillo*, he says *pin;* he says *stomach?* she says *stomaco*. And there you are; it's all over but the operation.

SWANZY'S HANDBOOK OF THE DISEASES OF THE EYE AND THEIR TREATMENT. Twelfth Edition. Edited by LOUIS WERNER, M.B., F.R.C.S.I., Senior Mod. Univ. Dub., Surgeon to the Royal Victoria Eye and Ear Hospital, Consultant Ophthalmic Surgeon to the Mater Hospital, Professor of Ophthalmology, University College, Dublin, and Examiner in Ophthalmology Dublin University. With Illustrations. Philadelphia: P. Blakiston's Son & Co., 1919.

THE present edition is the second which has appeared since the death of Sir Henry Swanzy. It contains more than a dozen new illustrations and twenty-seven pages more of text than the eleventh edition. A complete and careful revision has been made by the editor. The Diseases of the Cornea have been reclassified, and some additions have been made, including Superficial Linear Keratitis, the pathology and treatment of which are briefly discussed. Among other additions and improvements may be noted the description of Acne Rosacea Keratitis, Hypotony, a summary of the methods of diagnosis in Chronic Uveitis, and a *résumé* of the investigations of Dr. Gordon Holmes on the Cortical Center of Vision. Some of the operative text has been elaborated, notably the technique for excision of the lacrymal sac and for the transplantation of mucous membrane for trichiasis, and new operations have been added.

DAS HUNGERÖDEM. Eine klinische und ernährungsphysiologische Studie. Von Dr. C. MAASE und Priv. Doz. Dr. H. ZONDEK.. Mit 17 Abbildungen im Text. Leipzig: Georg Thieme, 1920.

AS the result of extensive metabolic and clinical studies of many cases of so-called "war edema," the authors consider that a better term is "hunger edema," since the condition is primarily caused by under nutrition. The lack of fat is especially important and this deficiency the authors believe leads to damage to the endothelial cells of the vessels which makes them more permeable. A contributing factor is the increased fluid intake which goes hand in hand with the reduction in food, for in order to obtain a feeling of satiety the population consumed large amounts of soup, coffee, etc., and the water content of the turnips which made up a large proportion of the dietary is also very high. Cold and fatigue were found to be additional inciting agents. The treatment consisted in rest in bed with the administration of food, especially fat and protein.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Fifty-Fourth Annual Meeting, Held at Spring Lake, June 15-17, 1920.

Arthroplasty, with Demonstration of Patients and Exhibition of X-Ray Plates.—Dr. GEORGE H. SEXSMITH of Bayonne read this paper, stating that arthroplasty was applicable to large and weight-bearing, as well as to small joints. Different interposing substances had been employed, but the only proper thing to use was an autogenous pedicled flap of sufficient thickness. The tendency of the short parts to contract must be overcome in the beginning by means of apparatus, or the operation would be a failure through causing too much pressure on the interposed tissue and destroying it. In operating on the knee, he included the entire lateral ligament, lateral displacement being prevented by proper preparation of the ends of the bone. He further stated that the result seemed to be one of great instability, but the operation gave a firm, weight-bearing joint by the end of six months. Six months should be allowed after the cure of infection before operation was undertaken; and in the case of tuberculosis, one year. He thought that the operation was safe and afforded great relief, but he did not believe that an absolutely perfect joint was ever produced by an arthroplastic procedure.

Dr. TWINCH of Newark said he had never tried deepening of the condyles. He thought that unless one turned the patella inside out, one would have union again.

Dr. BASSETT of Salem stated that he was convinced that where a good functional result was to be obtained, passive motion should be begun within ten or twelve hours. He had operated on some cases within ten or twelve hours and did not use any flaps at all. He said that the reason he began physio-therapy early in this joint was because of the embryonal osseous tissue that persisted in the capsule of this joint, as in no other joint of the body. In the so-called chip fractures one got, on the tenth day, a board-like mass, which was avoided if one began the treatment early. He thought that in all cases of fractures involving joints, it was important that these cases should not be immobilized so that the joint on either side of the bone fracture was fixed.

Dr. SEXSMITH said that in the first operation that he performed on the patient with the two knees, it looked as if the leg would have fallen off. She did not get infection, did not die, and she got a knee. That gave him courage to go after the other. In thirty days, this woman stood in front of the camera with her legs both under her. He said that it would be slow going in the case of a tuberculous joint, until after a year or two.

Heart Irregularities: Their Clinical Recognition and Interpretation.—Dr. CHARLES E. TEETER of Newark read this paper. He said that it was his purpose to attempt to elucidate the particularly important diagnostic criteria by which each form of heart irregularity might be recognized, as well as to indicate the symptoms and their relative degrees of importance. For a number of years, attention had been paid only to heart murmurs. These showed lesions of the valve, while arrhythmias showed lesions of the muscles, which are of much greater importance. The principal irregularities of rhythm are extra systoles—ventricular, auricular and nodal; alternating pulse; heart block, complete, or the Stokes-Adams syndrome; coupled rhythm, paroxysmal tachycardia, auricular fibrillation, and flutter. He said that formerly, if there was arrhythmia present, it was merely stated that the heart was irregular; but now the types could usually be approximated by bedside means, without the use of elaborate apparatus. Many of these patients were so acutely ill that elaborate apparatus could not be employed.

Dr. WALLACE of Montclair said that if one got the flutter cases digitalized they became totally irregular and a condition of auricular fibrillation resulted. Under digitalis they would frequently return to rhythm. They became normal again and stayed so for a longer or shorter time. There should be no misunderstanding as to the value of the electrocardiograph in the study of heart cases, but it was only one leg of the diagnostic tripod—the patient's history, the clinical diagnosis, and the electrocardiographic findings. He wondered how many had heard the auricles beat. He had heard them in an old man at the Mackenzie clinic. The patient's pulse was fifty to the minute; and between these beats one got the faint flutterings corresponding to the auricular contractions.

Dr. LATHROPE of Morristown said the heart muscle lesion was always the *sine qua non* of any case of cardiac failure. Any of the autopsies one saw on cases of cardiac failure would show very definite lesions in the heart muscles, as well as the associated lesions in the valves. He did not believe that patients died of valvular lesions *per se* He thought that they died of a weakened heart muscle, which was not able to compensate for the valve lesion. He stated that when one made a diagnosis of a heart muscle or heart valve condition, the first thing to bring into play was not digitalis, but common sense. He believed that a careful history with regard to heart cases was of more importance than the rest of the examination, because from that one learned just what that particular patient could do with that heart. If one removed the thing that was causing the damage and did it fairly promptly, one might be able to clear up the whole condition before actual gross changes had occurred in the heart.

Dr. GOLDSTEIN of Camden said we must not forget the older methods, for by the use of them we could make a fairly good clinical diagnosis of most of these arrhythmias. At present, one dared not rely too much on these instruments of precision, because he doubted whether there were more than two cardiac stations in the State, and he knew of no private physician who had an electrocardiographic outfit complete. He thought that an important thing was the group acquisition of these forms of apparatus.

Dr. MARVEL of Atlantic City asked Dr. Teeter what his observation had been in parxysmal tachycardia, whether he had found an increase of the fluoroscopic shadow in the transverse diameter of the aorta, and also in the ventricular shadow. Dr. Marvel stated that he had recently had an opportunity to watch two cases of chronic paroxysmal tachycardia, in which the shadows had been much increased and had changed in the interim between the attacks as much as two centimeters. He had been following the method of administering digitalis in auricular flutter and also in auricular fibrillation, for two years. He tried to regulate the amount of the drug to be administered by the action of the heart, and felt that guiding the amount administered by the results one obtained on the heart muscle was a much safer way to give digitalis than to give a definite amount for two or three days or a week in regular doses.

Dr. TEETER of Newark said digitalis was the most valuable heart remedy we had. Most of his patients had been so sick that he had not obtained an *x*-ray. He had always got clinical evidence of enlargement. Alternating pulse was very easily determined with the sphygmomanometer; and it was a matter of the greatest importance in prognosis. He said that nobody with an alternating pulse could stand a surgical operation.

Obesity.—Dr. FREDERICK C. HORSFORD of Newark read this paper. To become fat, he said, required an intake of food above the caloric needs, although not all people who ate more than the body required became fat. There was a great difference between simple overfatness and obesity, as the latter was pathological and probably of pancreatic origin. He said that the intermediate products of the metabolism of fats and of carbohydrates were similar in structure. In diabetes, there was enzyme formation and it had been suggested that in obesity the process was similar. He thought it was well to examine the urine from time to time so as to detect any tendency to alimentary glycosuria, so that the patient might be saved from diabetes. He further stated that it was very easy to transcend the food requirements. If people confined themselves to natural foods there would be much less chance of overburdening the system. For the complete combustion of fat, a large supply of oxygen must be furnished.

One should cut the fat from the diet, allowing the patients to use up their body fat. He suggested that it was well to have at hand a printed scheme of diet affording approximately nine hundred calories, with which to begin treatment. Heart weakness was only a relative contraindication to reduction treatment.

Dr. MARTLAND of Newark said that fat people died early. One saw at the autopsy table every day stout people who had died early deaths, many of which could have been averted. There were four classes of these cases. The first was exogenous, of which there were only two, overeating and lack of exercise. The second form was endogenous, which was usually due to abnormalities in the glands of internal secretion. Then there was a third class, the mixed. He stated that since obesity was a collection of fat between the muscles, there was a fourth form, with fatty tumors over various parts of the body and lipomas of the neck. Obese patients did not stand bacterial infections of the lungs, especially pneumonia. He thought that there were only three things in the treatment: The first was to cut down the caloric intake; the second, to increase the exercise; and third, if the metabolic rate was below normal, one could bring it up to normal by feeding thyroid and stimulating combustion, but in each case it should be found out whether one had an exogenous, an endogenous, or a mixed form

Dr. TEIMER of Newark said that one could not use protein beyond the requirements of the body for cellular growth and repair. Proteins conveyed in greater amount were simply used as fuel and after the caloric requirements were satisfied, were stored principally as fat. Nature had provided a number of wholesome checks against excessive overloading, furnished by the organs of elimination and of assimilation, and by a feeling of satiety. He said, however, that there were persons in whom these checks did not operate in the same degree or in whom they were overcome by artificial means, like stimulants. Persons who did not get fat from overeating were simply those in whom these checks were readily set in motion; their appetite failed as soon as they exceeded their usual consumption of food. He asked whether either of these conditions could be considered pathological. He agreed with Dr. Horsford that abuse of food would in time damage the organs charged with the metabolism of the abnormal amounts thrust upon them.

Dr. GOLDSTEIN of Camden stated that in adult males fat comprised about one-twentieth of the body weight. This proportion was greater in the female. Obesity required treatment only when symptoms of definite functional trouble of the organs or nervous system were present. He especially wished to emphasize the great amount of good that could be accomplished in cardiac insufficiency of the obese, as soon as the regulation of the food ingested and the energy expended was properly carried out. Obesity threw increased work on the heart and arteries and therefore played a very important rôle in the production of arteriosclerosis. As a substitute for sugar for sweetening in the treatment of obesity, he suggested the use of sodium benzosulphinide.

Dr. HORSFORD emphasized that overfatness was something to look on with suspicion. He did not think that every overfat person would become diabetic or develop cardiovascular lesions; but it was a disorder of metabolism, a toxemia; and a large number of people who suffered from obesity suffered from cardiovascular disease and hypertension and died a long time before they should.

Cooperation of the Specialist and the Family Physician.—Dr. LINN EMERSON of Orange read this paper, in which he said that in nearly 50 per cent. of the cases of fatal illness incorrect diagnoses were made, and hope for improvement in this respect lay in the specialists working in groups. He thought that under a plan of group practice it would be possible for a patient of moderate means to get a thorough examination at much less cost than he could if the separate specialists were consulted, one at a time. He went on to say that if the legislators would make a visit to some good clinic and see the results of the various examinations, they would not be so ready to listen to quacks. There should be a public medical service for industrial workers and their families, the compensation of the physicians engaged in this work to be regulated by the character of their work and the time given to it. He thought that a wise step would be the passage of uniform State laws licensing more than one grade of medical practitioner, thus shortening the period of preparation for those who wished to do only routine sanitary, public health, laboratory, or industrial work, and giving an opportunity for advancement to those who desired to become internists, surgeons, or specialists, with superior licensure for those who attained their greater proficiency. Hospitals and dispensaries should be largely under the supervision of the Bureau of Health, and all internes and members of the staff should be salaried. The heads of departments should receive adequate compensation, and if the service was not large enough to justify the use of the full time of these physicians, they should be compensated in proportion to the amount of time spent by them. Old-age pensions should be given to doctors, and they should be employed in departments of medical service for which the aged medical man was fit.

Dr. WILSON of Elizabeth stated that he wanted to emphasize three points in the paper: the Chiropractic Bill, Group Medicine, and Compulsory Health Insurance. He felt that it was necessary to deal with the Legislature in the only way that they could understand—through the ballot. He suggested that the Legislative Committee send the society the name of every representative who voted for the Chiropractic Bill, and that they try to see that these men were not returned. Group Medicine might result in commercializing medicine. Regarding compulsory health insurance, he had it on good authority that Lloyd George had changed his mind on the subject, because it had not come up to his expectations. The doctors in Germany and Scandinavia, and also in England, were said to be on strike. They were disgusted with this form of insurance over there, and were giving it up.

Dr. EMERSON of Orange felt strongly that the underlying principle of compulsory health insurance was right. There was nothing contrary to American institutions in it, provided it was carried out in a proper manner. He said that if we should have this thing there must be no distinctions, and that if we should socialize the whole medical profession we must pay them enough to justify the service that they rendered. There was nothing inimical to the medical profession in a service administered so that every individual might have medical service at the expense of the State, but the person who wanted the services of a doctor of superior skill and ability, and could pay a large fee might do so.

President's Address—The Doctor.—Dr. GORDON K. DICKINSON of Jersey City read his address. He said his object was to show that the affairs of men passed along in a determinate way. The time had come when the profession must wake up. The inevitable was with us, as it had been with the men in the past. If we kept our heads to the ground, grazing, forgetful of what must come, there would be disaster. Every man, whether a physician or not, should be a citizen; and the best one possible. He said there was no reason why a physician should not be also a politician.

Pulmonary Tuberculosis and Conditions Simulating the Same.—Dr. SAMUEL B. ENGLISH of Glen Gardner read this paper and said that if the tubercle bacillus was present the diagnosis could be made, and when it was not there was no other pathognomonic sign. While in adults a history of association or exposure might mean little, he thought that greater stress should be laid on it in the case of children. Too little attention was paid to previous illness, he said, and very often, in reaching back into the history we could find that a nervous breakdown, an exacerbation of grippe, or other condition, was really due to tuberculosis. Although little dependence could be placed on one or two negative returns, it was his observation that many patients were told, as the result of too few examinations of the sputum, that they had not the disease. The diagnosis of early disease should not rest on the presence of bacilli; but a diagnosis of advanced disease should be questioned, if the bacilli were not found. The absence of bacilli did not preclude a positive diagnosis. He stated that in early tuberculosis not only was there no single pathognomonic symptom, but there was no

single group of symptoms on which one might make a diagnosis. He thought that one could not exaggerate the importance of early diagnosis, because at that time the patient had the best chance of cure.

Dr. ARMSTRONG of White Haven, Pa., stated that physicians should endeavor to make correct diagnoses, among other reasons because the number of beds devoted to tuberculosis were inadequate to accommodate even active cases, not to speak of cases that were becoming active. At White Haven not more than 3 per cent. were turned away as being nontuberculous. The last report of the Trudeau Sanatorium at Saranac Lake stated that 8 per cent. were nontuberculous. Both of these were lower than the statistics that Dr. English had quoted. Dr. Armstrong said that the reason that theirs were lower than those of Saranac Lake was because they took patients for other reasons, while the latter insisted on taking only very early or incipient cases.

Dr. NEWCOMBE of Brown's Mills said that the infection of tuberculosis was most frequent in childhood before the tenth year. He considered it important to take a careful history and learn whether the child was breast or bottle fed, and whether it had had measles, typhoid, or pleurisy. Of those who had had blood spitting at any time 7 or 8 per cent. would sooner or later develop tuberculosis. He thought that if a physician had made a diagnosis of tuberculosis he should tell the patient what was the matter with him. It was better for the patient to know the truth early, when he had a chance to obtain an arrest of the condition. Too much attention was paid to physical signs and not enough to symptoms.

Dr. POLLAK of Secaucus said the Glen Gardner institution had been regarded by many practitioners as one in which only incipient cases were admitted, yet Dr. English had given figures which showed that only 8 per cent. were without positive sputum. If they had positive sputum, he said, they were out of the incipient class, and in the moderately advanced or advanced stage. He suggested that tuberculous patients be admitted to general hospitals, so as to give the physicians and nurses a chance to become acquainted with the disease.

Gastrospasm and Its Diagnostic Significance, with Lantern-Slide Demonstration.—Dr. J. ROEMER of Paterson read this paper. He said there were three varieties of gastrospasm: regional, circumscribed, and total. These might be differentiated under fluoroscopic observation and manipulation. The causes of gastrospasm might be either functional or organic, and intra- or extra-gastric. When accessible for recognition by means of the *x*-ray the spasm appeared most frequently on the greater curvature, a little below the cardia; but it might be found in any other part of the stomach; and several spasms might be present, dividing the stomach into compartments. He said that total gastric spasm was the rarest form and in most cases was of extra-gastric origin. Gastrospasm was characterized by extreme hypertonus. The stomach was considerably diminished in size and situated high in the abdomen. Peristalsis was absent, and the food was seen to pass almost continuously into the small intestine. He said the resemblance of all forms of gastrospasm to filling defects due to cancer was striking. Not only was the novice in danger of mistaking it for the latter, but the expert radiographer as well.

Dr. REISSMAN of Newark stated that there were two intrinsic causes of gastrospasm in which the surgeon was particularly interested, and these were ulcer and cancer. He also stated that when one found the ulcer it was immaterial whether the spasm was present or not; and when one had discovered the cancer by *x*-ray, it was equally immaterial whether there was spasm or not. When, however, one found a gastrospasm, a diseased area anywhere below the diaphragm should be looked for. He said anything below the diaphragm might cause a gastrospasm, particularly appendicitis and gall-bladder disease.

Dr. ROEMER of Paterson stated that the percentage of cases in which one found a penetrating ulcer of spasm were few. If he had made the diagnosis only from actually seeing the ulcer, he could not have made 20 per cent. of his diagnoses. The percentages of hypertonus and hypermotility were much higher, and these were far more important than was a direct visualization of the ulcer. He said that the only ulcer that was visualized was one that had penetrated the mucous membrane, making a sac leaving the mucous lining of the stomach. He further stated that most ulcers started as a small erosion; and in order to protect these small erosions, the stomach produced a spasm and a dilatation about the seat of the spasm.

Physical Diagnosis in Obstetrics.—Dr. JOHN FRANCIS CONDON of Newark read this paper. The importance of physical diagnosis in pregnancy was very often not appreciated, with the result that its neglect was a causative factor in the large morbidity and mortality in obstetrical practice. If a complete physical examination were made in all cases pathological conditions would be recognized and corrected before labor; and the treatment which seemed to occupy the main position in clinical obstetrics would not be an emergency treatment, but a well thought out plan in each case.

Dr. BUNTING of Elizabeth said that he really believed that there were a good many men in the State Society who had had an awakening with regard to obstetrics. He thought we were in the midst of a campaign for better obstetrics. People were looking around to find where they could get the best, not the cheapest. He was sure that there were members of the society who, as soon as they took up the work, and proved that they could do it, would be asked to join the staffs of a good many hospitals in New Jersey.

Diverticulosis of the Colon, with Special Reference to the Cecum.—Dr. M. W. REDDAN of Trenton read this paper. He said this condition was caused by Jackson's membrane, and not by pericolic bands, as formerly believed. It was frequently diagnosed as appendicitis; but appendectomy did not cure the patient. Diverticulosis of the colon was an exciting cause of diverticulitis, and subsequent cancer of the cecum.

The Problem of Venereal Disease Control.—Dr. J. F. WALLHAUSER of Newark read this paper, in which he said that very little success had attended efforts to regulate prostitution; on the contrary, the evil had grown worse. In every instance in which recognition by licensing had been tried, failure had been the result. Cooperation on the part of the public was greatly needed, and in education along proper lines there lay great possibilities for overcoming the evil. Sex education, if improperly managed, would do more harm than good, but the value of proper sex education had been proved. It had been a wonderful help in the army. During the war every effort was made by the Government as well as by the State and local authorities, to stamp out the evil, the matter being attacked from every angle. He thought these efforts should be continued in every locality, as was being successfully done in Newark. The main issue was that of public health, and not of morals. It was decided in Newark that it would be best to teach the parents, and let them impart the instruction to their children. The lessons learned had proved to be a cooperative force, in conjunction with the vice squad of the police department, in bringing cases to their clinic, which opened up a new field for detaining and reclaiming young prostitutes. Another important point was the early diagnosis of syphilis. The hope of preventing its later manifestations lay in recognizing the disease during the first month of infection. The longer treatment was delayed the less were the chances of cure. It was hard to impress this upon the patients, so he thought that enforced treatment was the only remedy. This brought up the matter of the reporting of venereal diseases, and the speaker thought that reporting by name and address was impossible of attainment, while reporting by number would be valueless for statistical purposes. In Massachusetts there had been a plan adopted by which the reporting was made dependent upon the patient's compliance with the direction of his physician. The present law of New Jersey had had sufficient trial to show that it will never fulfill the purpose intended. Prophylaxis, which had been so helpful in the army, could be applied to civilian life. As a public health measure, however, it could not be officially adopted, because it would be used as an excuse for permitting unlawful sex relations. In Newark there was a complete arrangement for taking care of venereal cases over a period of three years.

Dr. CASSELMAN of Camden said the eradication of syphilis could readily be attained by medical means, as it could be rendered practically noninfectious in less than two weeks. Gonorrhea was harder to control, because of the greater difficulty in rendering it noninfectious. He said health officers should require all delinquent patients reported to them by physicians to return for treatment. He thought reporting in any other way than by name and address would be a step backward. Personal prophylaxis was the cheapest, although not the best means of controlling the spread of venereal disease. It might be necessary to adopt it by reason of insufficient appropriations, in spite of the danger to public morals in such education.

Dr. SCHAUFFLER of Princeton stated that the army experience showed the importance of what Dr. Wallhauser had been emphasizing. Education and prophylaxis were the two main steps. Of these education was the most important. Prophylaxis was efficient in the army only because education went with it. He said that so it was with the education of the public that was at the bottom of all that we could do; and that education belonged to medical men primarily. Doctors did not know how to go to the people and tell them the facts in clear, concise language, so that the teachers might go ahead and impart the matter to their children, but they ought to sacrifice their time and inclinations and go to work on the subject.

Dr. KOPPEL of Jersey City said they had been reporting cases for two years, and it did not prove to be valuable except for statistics. He did not think it was of any use to either patient or physician. The report went to Trenton and was filed, and the health officer in his city did not know what happened to it. They insisted on reports and the physicians sent them to satisfy, he thought, the curiosity of the clerk. They had in Jersey City a detention hospital in connection with a clinic, and they did not let the acutely affected go out to infect others if they could help it.

Dr. CRASTER of Newark did not agree with Dr. Wallhauser in his gloomy picture of reporting. He felt that, just as was in the case of every other disease that was new in reporting, it was a question of getting familiar with the reporting of this thing. He hated to think that it would become necessary to adopt prophylaxis, but it might have to come to that. He hoped that physicians would appreciate the stand the Health Board was taking. It was trying to stamp out a contagious disease, one associated with a tremendous moral side. He said that without the cooperation of the physicians the health boards were completely helpless. They had to know that the physicians were helping them to make the disease at least controllable.

Dr. LIPPINCOTT of Camden said that it had been very striking to him to see how soon the men who were given educational advantages during the war had forgotten what was taught them. They came out of the army and the first thing they did was to contract either syphilis or gonorrhea. He had had so many men consult him that he had taken the trouble to ask whether they had forgotten their instructions along the line of prophylaxis. They had given him two answers: one, that they had been intoxicated and did not think about it; and the other, that they had gone to physicians and the doctors had said, "I do not care anything about that," and sent them off. Dr. Lippincott thought that prophylaxis, as we knew it to-day, was dangerous, because it gave a false sense of security. He did not see what good the reporting was doing. The statistics were not right, because a lot of physicians did not report their cases.

Dr. EMBURY of Basking Ridge said that sex manifestations were only one of the physiological functions that the human body performed, and it seemed to him that the basis of discussion should be, first of all, physiology, because we knew more about that than about the social or moral aspect of the subject. Masturbation in boys was more common than people were willing to admit, and the only reason that it was done away with in 90 per cent. or more of the cases was the establishment of regular sex relations on the part of the boys when they got older. He wanted to know what authority Dr. Wallhauser had for saying that continence was compatible in every case with good health. He thought that it was compatible with the health of some, but that this was true in the case of every man he could not believe.

Dr. GOLDSTEIN of Camden said that there was no doubt that a large percentage of human beings could be continent without having nervous symptoms and other complaints, but there was a small percentage who could not be continent without considerable trouble. He said that if they were going to report cases they ought to do it and not make a bluff at it. He thought that the reporting was necessary.

Dr. WALLHAUSER said that one would never get cooperation with force. He knew personally, from men in New York, that the syphilographers were not even diagnosing their cases in the office, for fear that someone would look at the records and they would be sued for not reporting them.

Cerebrospinal Fluid; Its Changes in Various Diseases and Their Significance.—Dr. E. G. HUMMEL of Camden read this paper. He said the changes in the cerebrospinal fluid in various diseases could not be generalized, and each disease presented at least some change peculiar to itself. There were three types of conditions that produced changes in the cerebrospinal fluid: meningismus, meningitis, and systemic disturbances. The changes in the cerebrospinal fluid which were found in various forms of meningitis differed from each other, not only bacteriologically and cytologically, but also physically, chemically, and physiochemically. He said the pathogenesis of meningitis must be dealt with separately in each form. While all the forms were produced by bacteria, the reaction of the meninges to the bacteria was different in each form. In meningism there was a purely mechanical disturbance; while in meningitis there was an infection, with destruction of the local tissues. In treating these various forms it was of the utmost importance that the remedy be brought into direct contact with the central nervous system, and as early as possible. The injection was made either intraspinally or intraventricularly. The intravenous injection of serum ought to be seriously considered, to produce sterilization of the blood for its possible influence on the meninges; but, when this was done the serum ought likewise to be injected into the cerebrospinal canal.

Dr. CASSELMAN of Camden said he would like to emphasize the value of the Pandy test, which was one of the simplest of laboratory examinations, and the most satisfactory method of determining the presence of an excess of globulin in the cerebrospinal fluid. The fluid must be absolutely fresh if it was to be examined for meningococci; but it was satisfactory, even if many days old, for the colloidal gold test for paresis. Dr. Casselman also said that usually the diagnosis ought to be made by means of the symptoms and physical findings, the specific changes in the cerebrospinal fluid being confirmatory. If the laboratory work was not done by the clinician himself he should tell the laboratory man what he suspected so that the latter might judge as to the best test to be used in the particular case.

Dr. GOLDSTEIN of Camden said as various other diseases might give rise to meningeal symptoms, meningismus, or serous meningitis, lumbar puncture which showed only a slight change in the fluid should not lead us at once to a diagnosis of meningitis or poliomyelitis, even if fever was present. He said that in every case of suspected meningococcus meningitis, one should culture the blood, because the bacteria might be found there while the cerebrospinal fluid was still bacteria free.

Dr. HUMMEL said it was very important for physicians to know the fluid changes that were noticed every day. They should associate their bedside findings with the labortory work. Bloody fluid was usually due to faulty technique. Sometimes headaches were produced because the equalization of pressure in the canal was changed; but, he said, no trouble would result, if the child were kept quiet until equalization of pressure had reestablished itself.

Essential Uterine Hemorrhage.—Dr. WILLIAM A. DWYER of Paterson read this paper. He said that in these cases the only pathological condition found in the endometrium was a hyperplastic mucosa with edematous stroma and cystic glands. The etiologic factors were sclerosis of the uterus, incoagulability of

the menstrual blood, and the influence of the ovary and corpus luteum. The uterus itself was a passive agent in the production of essential hemorrhage. He said that the activity of the corpus luteum as a causative factor was due either to stimulation or dysfunction of the gland. At the present time, owing to the lack of definite knowledge concerning the action of the glands of internal secretion, we were obliged to resort to either hysterectomy or a destruction of the follicular apparatus by radium or the *x*-ray.

Dr. ILL of Newark said that he knew of only one form of essential uterine hemorrhage, and that was in young girls, who started bleeding and bled for months and months, no matter what one did, and then stopped for months and months. The question of the corpus luteum being at fault was worth studying, but it should not be forgotten that the ovule ripened first, and that the corpus luteum was a secondary matter. Curettage had been very much overdone. At the same time, he thought that it was an exceedingly valuable adjunct to the physician's armamentarium. The congestion produced by excessive conception caused changes in the tissues which resulted in hemorrhage. He had done extensive work along the line of radium treatment and the ovary had gotten small first, and the uterus had grown small afterward. The menopause symptoms in these patients had been very severe. He said that he would rather remove the uterus and leave the ovaries than use radium. He believed that all these cases of hemorrhage could be made out to be anatomical, with the exception of the young girls.

Dr. FIELD of New York City said we often saw cases of bleeding of the uterus in very young persons in which every known means except extirpation had been carried out with utter failure, and if there was any means by which aid could be given to such persons without removing the organ, he wanted to discuss the advisability of using such a means before resorting to the knife. He said that in a series of eleven cases in young girls referred to the Radium Institute, radium had been prompt in checking the hemorrhage. Removal of the uterus was almost the last thing that should be undertaken in such cases. The very first action of radium was to produce a contraction of the blood vessels. The uterine body should be left alone and the ovaries should be rayed over first. A better contraction was gotten in this way than by direct uterine application. No one had proved that radium permanently caused sterility in a young person. At the most, two years and a half later, the patient got a return of menstruation. He did not, in such cases, find any unpleasant symptoms following the use of radium.

Dr. HARRIS of Paterson said that undoubtedy radium had great potentialities for harm; and in the case of a young girl great care as to the dosage should be taken. He believed that radium properly applied was the thing to be tried in any such cases.

Dr. LEE of Camden said that he believed in radium and used it; but he thought it a faulty and dangerous procedure to say that the first thing to be done was to employ radium when one had a patient with bleeding for which one could find no definite cause.

Dr. DWYER of Paterson said that if one examined the uterus of a woman of forty-two or three years of age who had given birth to children, one would probably find the same standing out of the blood vessels as in a woman from whom the uterus had been removed for sclerosis. The chances were that with an increased knowledge of radium, menopausal symptoms would not be as marked and disturbing as now. He thought that it was better to take out the uterus than to subject young girls to the nervous phenomena of the menopause.

A Study of Acute Infections of the Ear as Seen by the Physician.—Dr. J. CLARENCE KEELER of Philadelphia read this paper, in which he said that in former days knowledge of ear diseases was limited to two classes: those that could be cured by surgery and those that could not be so cured. He stated that there should be a close affiliation between the otologist and the internist, so that those suffering from an abscess might be relieved in the quickest manner; because the presence of pus constituted a great danger. He thought that it was of primary importance to determine which portion of the hearing apparatus was involved. He said that the physician should be equipped with a good light, so that he might determine whether the trouble was in the external auditory canal or in the middle ear. One of the best methods of treatment of affections of the middle ear consisted in incision under gas anesthesia and drainage. The most common trouble with the external ear was the presence of foreign bodies, which might be either animate or inanimate. The former were usually insects, which should be killed by drowning before removal was attempted. The removal of inanimate foreign bodies should not be attempted until the tissues had been shrunk. Infections of the middle ear might be acute or chronic catarrhal, or acute or chronic suppurative otitis media. Acute infectious diseases might cause chronic middle-ear infections. In such cases a free incision into the ear drum through the portion presenting the greatest bulging should be made. In that way complications and disastrous consequences would be forestalled. It was a fallacy to think that when the discharge had ceased the danger was over. Dr. Keeler emphasized the fact that in a purulent discharge from the ear that resisted the usual and established methods of treatment, even though the classical symptoms, such as pain, tenderness, swelling, and discoloration of the tissues over the mastoid were absent, one should ever be heedful of the demand for immediate surgery of the mastoid.

Dr. NORTH of Trenton said that in children who had measles, scarlet fever, and bad colds, it seemed advisable not only to give attention to the disease, but also to treat the nose and throat in attempting to stay the onset of acute otitis media and therefore save the little patient from a disease that would probably last the rest of his natural life. Strict attention should be paid to adenoids and infected tonsils as well as the teeth. He was much in favor of every practitioner making a routine examination of his patient's ears. It would not take a great deal of experience to become familiar with the use of the otoscope so as to tell whether there was inflammation of the external ear or drum. In the Trenton Clinic they had come to rely very much on *x*-ray findings regarding mastoid disease.

Dr. STEWART of Atlantic City said that the question of ear wax was one that came to practitioners at the seashore, largely because the wax was dislodged by the water, causing sudden deafness. The removal of the wax should be done carefully, not using a large syringe and not using a force that would break the drum membrane, or bring about irritation. The habit of filling the ear with peroxide of hydrogen ought to be condemned, because when it combined with ear wax, or pus, it caused pressure by the liberation of gas.

Dr. EMERSON of Orange said the general practitioner saw the cases of acute otitis before the specialist, in many instances, where the child was so sick that he could not give information as to the source of trouble. Physicians were often called to see small babies because the attendant had been unable to explain their pain and restlessness, and found acute otitis media, relief of which caused a drop in the temperature and relief of pain. In older children there was often obstruction of the Eustachian tubes. The tonsils were greater offenders in this than adenoids. The tonsil swelled up and by pressure on its side and extension by contiguity, one got a stoppage of the tube and an accumulation of fluid in the middle ear. The general practitioner, if called early, and if he knew how, could abort many of these cases. If the practitioner gave the child a good saline cathartic and ordered it put to bed it was the best thing to do, and he should also use a solution of adrenalin in the nose and give belladonna internally; then three-fourths of the cases would resolve and the drum membrane would not have to be punctured. If the patients did not get better immediately the drum membrane must be incised and the material allowed to escape. When the child got over the discharge he should not be allowed to go through another winter without having the tonsils and adenoids removed. Every child who had had an acute otitis media was almost sure to have another and repeated attacks; and even though a chronic suppurative otitis did not ensue, he was sure that many cases of so-called chronic otitis media in individuals in middle and late life were due to attacks of chronic

purulent catarrhal and suppurative chronic ottitis media in early life.

Dr. SCARLETT of Trenton said that the outer lining of the drum membrane was skin, and to pour drops into the external auditory canal was like pouring medicine on the outside of the skin. One had to get to the seat of the trouble. Frequently one could make out the bulging on inspection. Before the drum membrane ruptured, the part where it ruptured became necrotic. Then when the discharge ceased there was a hole in the membrane; but by incising it one got rid of the discharge and as the case progressed the parts came together. Then when it was entirely healed one could hardly notice the scar.

Dr. GOLDSTEIN of Camden said that he wished to emphasize the importance of examining the ears of children frequently in order that the cause of unexplained fever could be found. One should examine the ears and throats in all the little patients with fever.

Dr. KEELER of Philadelphia said that anyone operating on ears, noses, and throats, and on tonsils and adenoids, should have the cooperation of the dentist. He made it a universal rule to have all cases *x*-rayed. When he had a case of impacted wax and removed it he looked at the drum membrane because often there was inspissated pus. He stated that if one started an exacerbation of the condition by removing this wax one might have a malpractice suit on his hands. If there was a perforation the patient should be told that there might be a discharge following.

Oration in Surgery—Fractures.—Dr. WILLIAM L. ESTES of South Bethlehem, Pa., said that the most important methods of treatment for getting good functional results in simple fractures of the extremities were as follows: It was important to give the patient the benefit of a well-taken skiagram. Shock was often marked and required care in management. Early shock was due to nociassociation, and should be treated with morphine. Late shock usually meant hemorrhage. The pain was so severe in many cases as to exhaust the patient. One should place the extremity in a position to give ease, and then administer a full dose of morphine unless one was ready to put on the final dressing immediately. When the patient must be transported the limb should be fixed in the position in which it was found. Traction and fixation should be employed. He said that it was rarely necessary to confine the ends of a fracture so that they did not move at all. When a little mobility was allowed the fragments sometimes united better. If the surgeon was unaccustomed to treating fractures he should consult an experienced man before doing anything. One should never attempt to set a fracture unless splints or apparatus were at hand to retain it. The extremity should be fixed so that the ends of the fractured bone would not do further injury or occasion unnecessary pain; and nothing else should be done until the splinting could be done. Plaster of Paris moulded splints, put on during general anesthesia as soon after the injury as possible afforded the best means of fixation which should be done with the aid of the fluoroscope. Since the war doctors had been using suspension with the Balkan frame. When steady traction was necessary to retain the fracture during the application of the splint the Hawley table was good. With suspension the use of the Balkan frame was of value, but required skill in adjustment. In Buck's extension too little weight was usually employed; it was still a favorite method with the older surgeons. The Balkan frame suspended the fractured limb, and the extension was regulated by weight and pulley. Splints were not of so much value, except in the forearm. Massage might be begun as soon as the spasms had ceased. He stated that massage should be repeated every few days, as it shortened the convalescence. Operative treatment required especial skill. Children did not need operation, as a rule. The American Surgical Association's Committee on Fractures found that the anatomical recoveries were more numerous in the operated cases, but that the functional recoveries were better in the nonoperative cases. Although numerically in the minority, the surgeons who believed in operations had a large clientèle, and had especial opportunities for observing the end results. The treatment of fractures was a matter that still required a great deal of study. He urged simplification of methods and standardization of results. The mechanical devices were too numerous and too complex. A careful reduction under anesthesia and the application of plaster of Paris appealed to him as the most important elements in the treatment. The traction apparatus should be put on and retained until the plaster was hard enough to resist further displacement. In prognosis he thought it would be well to be cautious in predicting the results in any fracture of the long bones. The British seemed to get better results from the operative method than did the Americans. Men trained directly under Lane or Jones had done most of these operations, which might explain their good results.

The Cause of the Continued High Mortality in Intestinal Obstruction.—Dr. DAMON B. PFEIFFER of Philadelphia, Pa., read this paper, in which he said that the mortality of intestinal obstruction had not diminished appreciably in the last twenty-five years. The causes chiefly responsible for this were: (1) The deceptive character of the early general symptoms and signs; (2) a lack of appreciation of the deadly nature of the toxins generated by intestinal obstruction. A review of the recent work on these toxins emphasized the necessity of recasting the symptomatology of the early, curable stage. Operative measures had made but little progress in the last twenty years, and seemed to have reached approximately their final development. Until some method was found of directly combating the toxemia of obstruction, the only rational hope of an improved mortality lay in considering the condition as a "super-emergency."

Dr. COSTILL of Trenton said that if one were to get any improvement in the mortality of this condition, one should have to start by early recognition. He remembered when in appendicitis the surgeons waited until all the signs had appeared, which ended in death, before the case was turned over to the surgeon for operation. Dr. Costill stated that they were still doing the same thing very largely in these cases of intestinal obstruction. Physicians knew that the high mortality was due finally to a toxemia, but they did not know what that toxemia was, nor did it make any practical difference. Their only hope was in realizing that it could be dealt with only in a surgical manner. When the general practitioner began to realize that when he had a sudden attack of intermittent pain in the abdomen, with hyperperistalsis, it was time to seek the surgeon, a great step in the right direction would have been taken.

Dr. HARRIS of Paterson said that the most important thing for a physician to learn was that in these cases of intestinal obstruction one should do only one thing, which did not do any harm; that is, one should give enemas and let them run out through the tube. Anything the doctor liked could be used. One should give a pint and let it run out, and then inject a pint and a half. When most of this had been returned, one should give more, increasing a pint each time. In this way one could tell how far the obstruction was from the anus. The bed should have been put in the Trendelenburg position before the enema was given. The water should be allowed to run out through the tube. He said the bowel should be emptied as far as possible.

Dr. CHANDLER of South Orange said that Dr. Harris's advice was good for an early case that had lasted only a few hours; but it was a rule that he had made in his practice for twenty-five or thirty years, "When in doubt, operate." This was the best rule in intestinal obstruction of any sort. By waiting the life of the patient became imperiled.

Dr. DICKINSON of Jersey City said that most clinicians did not think much of auscultation of the abdomen. Usually that was so, but occasionally one could get the tinkle and the heart sounds distinctly at the pubes. The surgeon must then go on immediately. Dr. Dickinson stated that he should listen for these sounds, and be ready to operate. Plain water at 130° should be allowed to run in and out. At the end of twenty minutes one got not only evacuation of the bowel up to the stricture, but also stimulation of the sympathetic plexus, stimulation of heart action, diuresis, diaphoresis, and comfort of body and mind. Very often, also, one would get proper slumber for the patient, which would not be gotten otherwise.

Symposium on Focal Infection: The Hospital, the Doctor, and the Dentist.—Dr. FLETCHER F. CARMAN of Montclair read this paper, which was a plea to physicians, particularly those connected with hospitals, to look into the mouths of their patients, especially the sick poor found in the public wards, and therein find their diagnoses. Treating symptoms alone should be stopped, *e.g.* those arthritic, cardiac, nephritic, hepatic, gastric, and intestinal conditions; but, rather, the root of the trouble should be sought and treatment begun there. He made a plea to the dentists for their cooperation with the physicians in their respective communities, through the hospitals; so that they might become conservators of health primarily, instead of, as heretofore, simply conservators of teeth.

Etiology and Treatment of Mental Diseases, with Special Reference to the General Practitioner's Duty in Prophylactic Work.—Dr. HENRY A. COTTON of Trenton read this paper. He said that laboratory investigation of the so-called functional psychoses showed that a large percentage of them were caused by focal infections, principally of the teeth, tonsils, and gastrointestinal tract. Treatment by eliminating these foci of infection resulted in the patient's recovery. It was necessary that the infection be recognized before the mental symptoms began. When prophylactic work could be done by the physician before or after the nervous or mental symptoms developed, only 15 per cent. of these cases remained in the hospital, as against 60 per cent. previously.

It was very encouraging to hear a paper like that of Dr. Carman, since at the present day one felt that by far the majority of conditions were due to a toxemia, the result of infection. But infection was not limited to the teeth. He said that while one should lay stress on the teeth, those who limited their observations to the teeth alone would often be disappointed.

Dr. ROSEWATER of Newark said that one should stop practising medicine as it was done to-day. No one man was perfectly competent to do all this work, and no patient had money enough to run the gamut of all the experts that were necessary, so they must have group medicine.

Dr. GOLDSTEIN of Camden said that they knew that these patients would get improvement much more rapidly if their focal infections were treated. He could not, however, put a great deal of trust in the marvelous recoveries that occurred so soon after the removal of the focus infection. He did not see how cases of rheumatism and nephritis in which the foci of infection were treated, got well immediately. He asked if the entire source of infection was removed, what about the effects of the infection that had been existing for ten years?

Oration in Medicine. The Internist: His Duty to the Public, to His Patients and to Himself.—Dr. W. BLAIR STEWART of Atlantic City delivered this oration. He said that no physician could miss one medical society meeting without fear of missing something that would help him in the treatment of his next case. Many problems were solved by contact with others in the office, the society, and the clinic. Doctors owed it to their patients and to themselves to use every means to improve their knowledge and skill. When they referred a case to a surgeon, they should study the case with him, and insist on being present at the operation. He said that there was a new era in surgery, called team-work. The internist, the surgeon, and the laboratory man should study diagnosis together. Consulting work might be done at home, but the hospital was preferable. It should never be used as a place for the meeting of idle, jealous, and political medical groups. If the local hospital did not command the respect of the public, there was something wrong with the medical staff, the board of management, or both. The medical profession must realize the importance of a hospital for the good of the public and not for the benefit of a clique. Preventive medicine would be the practice of the future, and it was necessary to educate the people as to how to maintain good health. Dr. Stewart further said that if merchants would give more study to the sanitary housing of their employees, their workers would not have to lose an average of nine days a year from preventable sickness. Tuberculosis, typhoid fever, and many other diseases had no excuse for their existence other than ignorance. With the extraction of one's teeth, the enucleation of tonsils, the sacrificing of appendices, one did not know definitely where one was, or how much would be left of one's body in future generations. One should not forget the social side of life by allowing engagements, other than emergencies of birth and death, to interfere.

Focal Infections in Relation to Eye Disease.—W. D. OLMSTEAD of Trenton read this paper in which he said that one could trace nearly every disease of the eye to one of the three or four sources of focal infection. He had presented this paper to reiterate and emphasize that which had been written on the subject, and principally to draw attention to the close association of focal infection and eye diseases. A true appreciation of this would enable one to solve many a previously puzzling optical enigma. He urged the value of a careful, painstaking examination in every case, as a routine procedure.

The Election of Officers resulted as follows: *President*, Philander A. Harris, Paterson; *First Vice-President*, Henry B. Costill, Trenton; *Second Vice-President*, James Hunter, Jr., Westville; *Third Vice-President*, Wells P. Eagleton, Newark. The Society will meet next year at Atlantic City.

THE AMERICAN PEDIATRIC SOCIETY.

Thirty-second Annual Meeting, Held in Highland Falls, Ill., May 31, and June 1 and 2, 1920.

THE PRESIDENT, DR. THOMAS W. SOUTHWORTH OF NEW YORK, IN THE CHAIR.

(*Concluded from page* 374.)

Has Malt Soup Extract an Antiscorbutic Value?—Dr. HENRY J. GERSTENBERGER of Cleveland presented this paper. He stated that while making a study of the respiratory quotient of scorbutic infants, it was decided for certain definite reasons to feed these infants on Keller's malt soup extract. This mixture, as was well known, had made for itself a record of producing and never curing scurvy. During this study three infants with marked and severe scurvy recovered unexpectedly in a rapid and complete manner. This surprising occurrence was probably due to this special lot of malt soup. Dr. Gerstenberg discussed various factors in the manufacture of malt soup preparations that might have had an influence in imparting antiscorbutic properties.

Dr. JOSEPH BRENNEMANN of Chicago said it was extremely difficult to say why some foods cured scurvy and others did not. It seemed that some children were cured of scurvy by almost any change of diet. Individual susceptibility seemed to play a large part in determining which children would develop this disease. The more one studied scurvy the more keenly he felt that the present hypothesis failed to explain many things in connection with this disease.

Dr. J. P. CROZER GRIFFITH of Philadelphia said that many members of the society would remember the oft-quoted statistics of their "Collective Investigation upon the Cause of Infantile Scurvy." In this there was nothing more evident than that there were various different dietetic conditions which were capable of producing the disease. Some children developed scurvy on pasteurized milk, some on boiled milk, some on raw milk, and some even on breast milk. Some recovered when pasteurized milk was changed to raw milk, and some, curiously enough, when raw milk was substituted for boiled milk. This committee reported that the only justifiable conclusion was that there was something wrong with the diet, but that what this dietetic error was did not appear clear. It was beyond question, however, that there must be besides diet a peculiar disposition to develop scurvy seen in a comparatively small number of infants. If this were not the case we would find all the infants fed on a certain mixture or proprietary food developing the disease. Malt soup had been a favorite food with him for many years, and he had seen only two or three cases develop scurvy in spite of the fact that no orange juice was administered. He thought malt soup was not to be blamed for scurvy more than other foods.

Dr. CHARLES GILMORE KERLEY said he was somewhat surprised to hear these things, for it was his experience that more cases of scurvy in infants were caused by malt soup than by any other method of feeding.

Dr. THOMAS S. SOUTHWORTH thought this subject should be very thoroughly discussed before the impression was conveyed that malt soup extract was an antiscorbutic. In one institution in which malt soup extract had been used for some years because they obtained better results with it than with lactic acid milk, they had had repeated outbreaks of scurvy when the management of the institution had failed to provide sufficient orange juice or tomato. It was absolutely imperative that infants receiving malt soup should have orange juice or tomato in considerable quantity.

Dr. GERSTENBERGER said he was thoroughly in accord with Dr. Southworth in believing that it would be a mistake to give the impression that malt soup extract was an antiscorbutic. He had made the report because it had suggested the possibility that there was something in the preparation of this special lot of malt soup that had caused it to possess antiscorbutic properties, and that if they could find out what this was it might be possible to manufacture a malt soup preparation which would not cause scurvy in case orange juice or tomato were omitted from the diet.

The Medical Supervision of the Boarded-Out Child.—Dr. MAYNARD LADD of Boston presented this communication, in which he described the work of the Boston Dispensary, which was administered through the cooperation of the Boston Children's Aid Society and the Church Home Society, two large child-placing agencies. This cooperative plan had served to demonstrate the value of expert continuous supervision of children in the care of child-placing societies and the value of utilizing for this purpose the equipment and medical staff of an organized dispensary, including specialties in all the chief branches of medicine and surgery, as well as clinical and *x*-ray laboratories for modern medical diagnosis and treatment. Dr. Ladd presented a statistical study of 876 individual children cared for by this organization. They were caring for about 500 children a year. Of these about 15 per cent. were sufficiently ill to require hospital care. This might be taken as a fair estimate of the hospital requirements of such a group of children. A little less than one-third of the hospital admissions were for necessary tonsillectomies and adenoidectomies. The death rate among these children was 1.1 per cent. This was undoubtedly due to the prompt detection of serious cases of illness and the facilities provided for early and, if necessary, prolonged hospital care. These statistics offered proof of the practicability of reducing the death rate of a supervised group to a point below that which was accepted as normal for the community. This clinic provided what every child ought to have, but few received: (1) A complete physical examination when accepted by the society. (2) Correction of defects which interfered with proper nutrition and development. (3) Prescription and supervision under trained nurses of proper diet, especially for infants and children in the second and third years. (4) Provision for meeting promptly cases of acute illness occurring in foster homes. (5) Examination on discharge with analysis of the history of the child under this care and transmission to parents and guardians through social service agency of the data in regard to the child's state of health and the subsequent care he should receive.

A Twenty-four Hour Schedule for Boys.—Dr. RICHARD M. SMITH of Boston presented this paper. He said that in a previous article entitled, "A Health Study of a Boys' School" (*Am. Jour. Dis. of Children*, October, 1919), he had drawn attention to certain fundamental principles with reference to the care of the health of school children and had pointed out lines for the further extension of health supervision. A table for the distribution of the boy's time during school hours between study, activity, and inactivity, was therein reported. A further use of this table had convinced them that it gave a correct distribution of the boy's time. The parent, the physician, and the teacher were together responsible for the child's life, and no part of that life could be arranged intelligently without the cooperation of all three individuals. His educational work in school must be arranged bearing in mind not only the studies necessary for the school curriculum, but whether also he was doing work at home, such as music and the languages. His exercise was made up of what he did at home in the afternoon quite as much as of the carefully arranged athletics at school. At the Rovers Open Air School for Boys a study was made of the weekly twenty-four hours' distribution of the time of the boys. The matter of time distribution and the question of instruction were the two most important factors in the health of school children. There were no means at present of determining whether or not a given boy was distributing his time in conformity with a healthful management. Dr. Smith presented a table which demonstrated what appeared to be a healthful distribution of the hours of the week, based upon data from the actual school schedules and statement made by the parents concerning the time spent at home. This table showed the following: A boy of six years spent about 40½ hours per week in study and exercise, and 127½ in recreation and sleep; a boy of eight years spent 48½ hours in study and exercise and 119½ in sleep and relaxation; a boy of 10 years spent 55 hours in study and exercise and 113 in relaxation and sleep; a boy of 12 spent 62½ hours in study and exercise and 105½ in relaxation and sleep. This represented what an average healthy boy of a given age could do who was taking enough school work to advance in his grade and who was having sufficient exercise to keep in good condition. It was possible for a child to have a schedule different in every respect from this average, yet be in normal health and progress satisfactorily in school. Such a child was obviously unusual and certainly could not be taken for a model for others to follow. Dr. Smith believed the principles involved in these tables were correct and hoped they would be used sufficiently so that correct principles might be inserted if those given needed modification.

A Study of Breast Feeding in the City of Minneapolis.—Dr. JULIUS P. SEDGWICK of Minneapolis presented this paper. He said that in their private work and in the clinic they had been using certain principles to encourage breast feeding and to maintain the supply of bresat milk. These were presented before the American Medical Association in 1917. The present communication dealt with the results of their efforts to apply these principles on a larger scale. They wished to ascertain what statistical results they could show as a result of the application of these principles as to the proportion of mothers nursing their babies and the effect on the infant mortality rate. In their endeavor to promote the supply of breast milk they had found that the most effective means was to make a demand upon the breast, though they also took advantage of other well-known means that might be of assistance. They felt that making a demand upon the breast by expression of the milk was often a most important factor in maintaining the supply. The technique used in expression was not that of going over the whole gland tissue and using massage, but consisted simply of emptying the sinus back of the colored areola. Expression was especially indicated in obtaining a supply of breast milk for premature infants or when for any reason the infant could not take the breast, or the mother's nipples were inverted, fissured, or sore. The other part of their plan consisted in reaching the public. This they had accomplished by gaining the cooperation of the medical profession, the health department, the infant welfare society and that of prominent citizens. The mother of every infant born in Minneapolis during the year was either seen by a representative of the organization or reached by mail or telephone. Each mother was given information and literature, and was followed and seen or heard from every month, or oftener if necessary. As a result of this work 96 per cent. of the babies born in Minneapolis were on the breast, and the mortality had dropped from 71 to 65 per cent. for that year.

Dr. ROOD TAYLOR of Minneapolis stated that although Dr. Sedgwick had reported on this subject before the national societies only the last two or three years, he had been preaching this doctrine and doing this work for a much longer time. He was under the impression that a large proportion of the work done by

pediatricians had to do with the artificial feeding of infants; in private practice in Minneapolis that field of pediatrics formed a very small proportion of their work.

Dr. CHARLES GILMORE KERLEY of New York thought it was a question whether infants nursed nine months did better than those nursed only three or four months. It would be interesting to know the condition of the infants nursed nine months in comparison with those in which there had been earlier weaning and bottle feeding.

Dr. H. M. MCCLANAHAN of Omaha referred to an investigation he had made showing that most mothers weaned their babies because some doctor had advised that course. He thought they should first do missionary work among the doctors, for most mothers were willing to nurse their children unless advised to the contrary. Dr. McClanahan recalled a paper he had read showing that the morbidity of breast-fed babies was considerably less than that of bottle-fed infants.

Dr. RICHARD M. SMITH of Boston questioned whether expression of milk as a factor in securing these results had not been overestimated. Was it not possible that these results were due to awakening attention to the value of breast feeding? He thought that with this work as an incentive breast feeding would be used much more than ever before.

Dr. LANGLEY PORTER of San Francisco said he had considerable experience with cattle that suggested certain questions in reference to breast feeding. There were certain cows that produced a high-grade milk and certain others that produced a low-grade milk, and the same was true of human beings; there were certain families that produced milk well and certain others did not. In certain individuals the function of producing milk was so poor that it was not worth while expending time and effort that were destined to fail. Dr. Sedgwick was fortunate in having to deal with Norwegians and Swedes who were naturally better nurses than the modern American woman. Another factor that tended to reduce the milk supply quite as much as disuse was overstimulation. It was just as important to pay attention to that side of the question as to see that the breast received proper stimulation. Dr. Sedgwick's method, however, was most effective.

Dr. SEDGWICK, in closing the discussion, said he regretted that they had not been able to get the weights of these babies. They had been very careful, however, to see that every baby received enough nourishment, and they had used both complemental and mixed feeding. As to the overstimulation, there might be a few instances of overstimulation, but they were very few in comparison with those who were understimulated. With reference to the feeding interval, they had used four-hour intervals, and four-hour expression of both breasts, if necessary. If the breasts were alternated every four hours that meant that each breast was stimulated only every eight hours, and frequently that was insufficient to maintain the milk supply. As to diet, they were very simple in their directions. They told the mother that she *could* have whatever her husband *should* have. She required a few more calories, however. Continued stimulation was more important than the ingestion of large amounts of fluid.

The Fate of Subcutaneously Injected Red Blood Cells.—Dr. ROOD TAYLOR of Minneapolis contributed this paper, in which he said that modern transfusion methods so successful in adults were mechanically less satisfactory in small infants. Thirty years ago studies were carried out which indicated that blood injected subcutaneously or intraperitoneally reached the circulation at least in part. Subsequent work by others on the whole had supported these early findings. In the present study large amounts of citrated blood were injected subcutaneously into six children. Thereafter there was an increase in hemoglobin percentage which was, as a rule, most marked after two weeks. There was usually no great increase in the number of red blood cells. The red blood cells of two children were counted before and after the injection by Ashby's method, serum which agglutinated the patient's own corpuscles but which did not agglutinate the injected corpuscles being used as diluent in the hemocytometer. The results showed that within five days after the subcutaneous injections of homologous citrated blood there was no marked absorption of the injected cells into the patient's circulation.

Recent Studies of Blood Nitrogen in Infants and Children.—Dr. FREDERIC W. SCHULTZ of Minneapolis presented this study, which had for its object the establishment of normal figures for the nonprotein nitrogen content of the blood in infants and older children. Practically no complete studies on normal children were available; such figures were, however, available for normal adults as the result of the work of Professor Folin. In the present study determinations were made of the total nitrogen, (urea, uric acid, creatinine, combined creatin and creatinine, and of the blood sugar. The amino acid fraction was being studied, but the results were not yet ready for presentation. The methods used were those of Folin. An effort was made to have the material as normal as possible. In infants under ten months the blood was taken from the head sinus; in older children from the median basilic or external jugular. Ten cubic centimeters was usually taken, which was sufficient for all determinations, and even allowed of repeating some. All determinations were carried out within twenty-four hours. The blood was taken from two and one-half to seventeen hours after the intake of food. The children were arbitrarily divided into five age groups as follows: From 1 to 6 months, 7 to 14 months, 2 to 6 years, 7 to 10 years, and from 11 to 14 years. There were in all 88 cases. A chart was presented showing the maximum and minimum figures for the different age periods, and all gradations between. It was found that the total nitrogen ranged from 24.90 to 41.10 mg., the average being between 32 and 34; for adults Folin and his coworkers found 24 to 32 mgs. The urea ranged from 10.80 to 20.40 bg., the average being about 15.50 mg.; for adults the average was between 10 and 23 mg. The uric acid varied from 0.55 to 4.75 mg., the average being about 2 mg.; the average for the adult was from 2 to 3 mg. Creatinine ranged from 1.110 to 2.055 mg., the average being about 1.4 mg.; the average for the adult was 1.1 to 1.3 mg. The creatin and creatinine ranged between 4.74 and 8.92, with an average of 6.5 mg.; the average for the adult was 6.5 to 9.5. The blood sugar ranged between 0.05 and 0.14 per cent., with an average of about 0.09 per cent.; the average for the adult was between 0.06 and 0.12 per cent. Thus the constancy of the nonprotein nitrogen excretion during the periods of infancy and childhood corroborated the findings for normal adults. This was true for all the components except for uric acid, which showed the same variability it showed in adult blood.

The Calcium-Magnesium-Phosphorus Balance in Children Subject to Convulsive Disorders.—Dr. B. RAYMOND HOOBLER presented this paper, in which he stated that the group studied were those classified as epileptics of the petit mal type. None of them gave a history of epilepsy in the family. The question was therefore whether they had epilepsy or some other convulsive disorder. A search of the literature failed to reveal satisfactory data as to normal balances for these substances, so they had first attempted to establish their own normal values for comparison with children of the same ages and weights to be studied. It was found that nearly every one of these children subject to convulsive attacks had a low balance in either magnesium, calcium, or phosphorus, but in none was the balance lowered in all three substances. By estimating the percentages of retention and absorption one could come very close to the actual state of mineral metabolism. In convulsive disorders of this type a search should be made for mineral deficiency, either in calcium, magnesium, or phosphorus, and if such a deficiency was found the attempt should be made to bring it up to normal.

The Circulatory System in Nutritional Disturbances.—Dr. W. MCK. MARRIOTT, Dr. H. MCCULLOCH, and Dr. K. UTHEIM of St. Louis made this contribution, which was presented by Dr. Marriott. He stated that in that particular nutritional disturbance known as athrepsia or marasmus it was very evident clinically that some changes in the circulation had occurred. This was recognized by the low surface temperature, slow pulse, and grayish color of the skin. It had

seemed desirable to estimate quantitatively the degree of circulatory changes and, if possible, to determine the cause of the changes. In measuring the circulation they had used the calorimetric method of G. N. Stewart. Before applying this method to infants they had applied it to animals and compared the results with those obtained by the Ludwig "Strohmühr." The method was easily applied to infants. In a series of 29 normal infants the average flow of the blood was 17.2 c.c. per 100 c.c. of arm per minute. In applying the method to 35 athreptic infants the volume flow of the blood was found to be very greatly diminished, sometimes being as low as 1 or 2 c.c. per minute. As these infants improved the volume flow of the blood increased and in some instances became normal. The next question to answer was regarding the cause of the decrease in circulation. One cause of diminished volume flow of the blood is known to be a decreased blood volume. The next step was to determine the blood volume of normal and athreptic infants. In a series of normal infants the average blood volume was 9.1 per cent of the body weight, the variations being from 8 to 10.8 per cent. The average blood volume of a number of athreptic infants studied was 8 per cent. of the body weight. One showed as low as 4.8 per cent. As adipose tissue was a relatively nonvascular organ, none would expect a thin infant to have a larger amount of blood per kilo of body weight than a fat one. They found the reverse to be often the case. This indicated definite decrease in the volume of the blood. The lowered blood volume was sufficient to account for the low volume flow in at least some of these infants. Other factors, however, seemed to be probably operative. The peripheral volume flow of the blood would be decreased if capillary or arteriolar constriction had occurred. They found such a constriction to occur in these infants. This was shown by the fact that there was a piling up of blood corpuscles on the capillary side. Blood obtained by a prick in the skin of these infants showed a distinctly higher hemoglobin in red and white cell counts than blood obtained directly from the veins. This constriction of the arterioles leads to poor peripheral circulation, and probably to the gray color of the skin. It also accounts for the fact that some of these extremely athreptic and apparently anemic infants had normal red blood cell counts when determinations are made on capillary blood. They considered the arteriolar constriction as a compensatory mechanism to maintain blood pressure when the blood volume was diminished. They found this mechanism ordinarily sufficient to maintain the blood pressure, as they very rarely observed low blood pressures in the athreptic infants studied. Having considered the changes in the blood and in the vessels, they next turned to a consideration of the heart muscle itself. This it might be expected would atrophy with the rest of the body, but at post mortem very little change in the heart muscle could be made out. It was possible, however, that functional changes might occur. To determine whether or not such was the case, electrocardiograms were made and in a certain number of the infants definite changes in the functional activity of the heart muscle were demonstrated. The variations from the normal most frequently observed were low amplitude of all waves. The P and T waves were frequently absent, especially in leads 1 and 3. The P-R time was found to be as long as 0.2 seconds, and the Q-R-S time was frequently prolonged. The ventricular complexes were occasionally abnormal in form, the R wave especially being notched. With improvement in the clinical condition of the patients the form of the electrocardiograms changed and this suggested that the alterations in the heart muscle were functional rather than organic. They suggested that poor circulation through the coronary arteries was in part responsible for the changes, a vicious circle being thus established. Some experiments were done on animals in an attempt to reproduce the athreptic condition. After a period of complete starvation, the blood volume of rabbits was found to be definitely decreased and also the volume flow. When the animals were again fed they maintained a constant weight for a considerable period of time until the blood volume slowly increased. After this the process of repair became more rapid. In some animals the blood volume did not return to normal and these animals failed to recover their weight and finally died.

Electrocardiography in Children.—Drs. MAX SEHAM and FREDERICK W. SCHLUTZ of Minneapolis covered in this paper, first, the physiological peculiarities of the normal electrocardiograms of all ages of childhood, including the premature, from one hour to thirteen years; second, the pulse period in 50ths of a second in all ages; third, the transmission time of both auricle and ventricle; fourth, diseases peculiar to childhood. The electrocardiogram at birth was constant. All of the new-borns, 22 in number, showed similar curves. A right ventricular preponderance was characteristic, showing a deep S, and a high R_1. During the first three months this form persisted. During the fourth month the S became smaller than the R in Derivation 1, signifying a change from right to left ventricular preponderance. From the fourth month to the end of the first years it gradually changed into the adult type. From the first year on the adult characteristics persisted. In the premature the form of the electrocardiogram was incomplete. All of the deflections except S were not seen. After birth all of the deflections in both the auricular and the ventricular complex were well established, and in practically all instances showed on the tracings. The pulse in newborns was quite regular, as was shown by the electrocardiograms. Sinus arrhythmia was not complete until the school age. From this time until puberty it occurred in about 50 per cent. of all normal children. By measurement of the P-R intervals and the R-T intervals the transmission time could be accurately studied. The average P-R in newborns was 0.10 of a second, from two to five years it was 0.12 of a second, and from six to thirteen years it was 0.28 of a second. This included the Q-R-S period, which in the respective ages was from 0.03 of a second to 0.09 of a second. The electrocardiograph was not only of value in pediatrics for the normal, but it was a great aid in diagnosis in abnormal conditions. A study of 22 congenital heart lesions, two of which came to autopsy, showed that only in cases in which the right side of a heart was involved, especially pulmonary stenosis, there was a characteristic right ventricular preponderance shown. In seven of eleven drop hearts, all of which were confirmed by *x*-ray, the ventricular complex in lead 1 was unusually low. Exudative diathesis decomposition, hypertrophy of the heart when unassociated with heart murmur spasmophilia, tuberculosis of the lungs, and other miscellaneous diseases were studied in 300 cases.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

NORMAL HISTOLOGY. By GEORGE A. PIERSOL, M.D. 418 pages, with 438 illustrations, 88 of which are in color. Published by J. B. Lippincott Company, Philadelphia.

ÉTUDE CRITIQUE DE L'ETIOLOGIE DES BRONCHITES CHRONIQUES AVEC SCLEROSE PULMONAIRE. By JACQUES DALSACE, M.D. 132 pages.

MORTALITY STATISTICS (1918), 603 pages. Nineteenth Annual Report.

THE EXTRA PHARMACOPŒIA OF MARTINDALE AND WESTCOTT. Revised by W. HARRISON MARTINDALE, Ph. D., Ph.C., F.C.S. and W. WYNN WESTCOTT, M.B. Lond., D.P.H.. Seventeenth Edition. Vol 1. 1115 pages. Published by H. K. Lewis & Co., Ltd., London, 1920.

THE ACCESSORY SINUSES OF THE NOSE. By ROSS HALL SKILLERN, M.D. 418 pages, with 300 illustrations. Published by J. B. Lippincott Company, Philadelphia.

CHIRURGIE RÉPARATRICE ET ORTHOPÉDIQUE Edited by MM. E. JEANBRAU, P. NOVÉ-JOSSERAND, L. OMBRÉDANNE, and P. DESFOSSES. In two volumes. Vol. I, 659 pages with illustrations. Vol. II, 656 pages with illustrations. Published by Masson & Cie,, Paris.

MAMMALOGY—AN ANATOMICAL AND TAXONOMIC CONSIDERATION OF THE GROUP TO WHICH MAN BELONGS.

BY R. W. SHUFELDT, M.D., C.M.Z.S., ETC.,
WASHINGTON, D. C.
MAJOR, MEDICAL CORPS, U. S. ARMY.

WHILE residing in New York City a number of years ago, I prepared an extensive and illustrated work on *The Game Mammals of the United States.* Had it been printed in the form planned, it would have been an exhaustive treatise on the entire group of our so-called game mammals—all the way from a chipmunk to an elk. Unfortunately I had made the work too exhaustive for the American publishers and presses; so the years slipped by, and the MS. and some 150 fine illustrations could not gain a place in the light owing to the national vice of commercialism so rampant in this country.

A few years before the outbreak of the world war, and at the time when Germany's output of scientific and semi-scientific literature was at its height, I made the attempt to bring the work out in that country, but succeeded only in part. Dr. E. E. Leonhardt, Curator of the Zoölogical Museum of Dresden, translated into German for me all the chapters treating of the mammals themselves, while the classificatory parts and the anatomy were both omitted. These translations appeared in *Natur und Haus,* a Berlin magazine having but a meagre circulation in the United States. The classificatory scheme of the Class Mammals, also extracted from the original MS., appeared in a modest little natural history magazine in Christiania, Norway,—a publication that claimed no circulation in this country whatever.

Recently I have published one or two of the main chapters in *American Forestry,* the official magazine of the American Forestry Association, having its headquarters in the Maryland Building at Washington. Such other chapters as possess interest to foresters will, as the editor of that publication, Mr. P. S. Ridsdale, informs me, appear in subsequent issues. This leaves the anatomical and classificatory part still to be taken care of; and upon reading this carefully over, at this date, I find in it and in its illustrations, so much of value to human and comparative anatomists generally, including veterinarians, that that matter appears to be worthy of a place in some standard American journal having a wide circulation among the various representatives of those departments of general medicine.

It may be of interest to record the fact here that the original work was, by permission, dedicated to Colonel Theodore Roosevelt, who made a personal effort to bring it out but was unsuccessful. The correspondence on the subject is still in my possession, and is really an interesting bit of history. The Colonel approved of the following text of the dedication, it being "in recognition of the far-reaching influence he has ever exerted in advancing the Biological Sciences, and especially that of Mammalogy, through his personal contributions to those sciences, and through his North and South American and African explorations."

With these few words to stand as a Foreword, the information embodied in that part of the aforesaid manuscript is here offered to the readers of the MEDICAL RECORD.

As Ichthyology is the science of Fishes, Ornithology the science of Birds, so is Mammalogy the science of Mammals. We find the word mammalogy to be derived from the English word mammal and a Greek word, *logos,* meaning a discourse or a treatise. Again, the English word mammal is derived from a Latin word, *mamma,* which is the term applied to the breast of a mammiferous animal. The Mammalia, then, is a group of vertebrated or backboned animals that, in addition to other special anatomical characters, possess breasts, whether those breasts are fully functional, as in man, or only rudimentary, as in the Australian Duckbill (Ornithorhyncus).

Now to comprehend fully our definition for Mammalogy, it is necessary to know what is meant by a science or by the word science. Science (from the Latin word *scientia,* knowledge; *scio,* to know), or what constitutes the science of any subject, is the knowledge of amassed or observed facts in relation to that subject. It means even more than this; for it implies that this knowledge has been systematized, set in order, severely tested and coördinated after rational methods, so that the observed facts are presented to our minds in their true relations. Biology is the science of life or living animals, and mammalogy is one of the special sciences of biology, —and so are ichthyology, ornithology, and others.

Mammalogy, then, a special science or department of biology, consists in a rational digest of all the observed facts in regard to the science of mammals.

It is an exposition of all that we know of this class of animals, systematically arranged, and includes the logical inferences of what still belongs to the realm of the unknown in regard to them. It has to do with, or treats of, the anatomical structure of morphology of mammals, both existing and extinct; of their physiology, and of their psychol-

ogy or mental attributes. The science of extinct mammals, however, is usually relegated to the special department of palæontology or palæomammalogy; for it is evident that we can know only through logical inference what most of the ana-

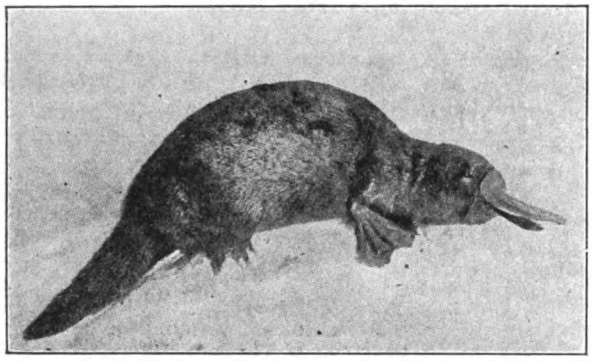

FIG. 1.—The Duck-billed Platypus. (After W. Saville-Kent, F.Z.S.)

tomy, all of the physiology, and the mental attributes of extinct mammals were like, except in cases where those mammals came under the observation and examination of science prior to their extinction. Mammalogy also treats of the natural habits of existing mammals, and their behavior under all sorts of conditions, both normal and abnormal. It takes into consideration their geographical distribution both in times past and present; it concerns itself with the geological record of mammals, their sequence in time, their ancestry, and their probable origin. It defines the relations and interrelations of all species and subspecies of mammals, as far as possible, of those still existing, and, by deduction, their affinities with those now extinct. It treats of the relations of mammals to all other groups and classes of all other animals in nature, and therefore includes also their taxonomy or classification. In fact, mammalogy aims to elucidate the true significance of this group of vertebrates in nature, and their place, relatively speaking, in the system.

This brings us to the point where we must define what a mammal really is. In ancient zoölogy they were generally referred to as "The *beasts* of the field,"—an utterly meaningless epithet at the present time. Far more recently they have been designated as the Quadrumana, and as *quadrupeds*, meaning, of course, that they were all "four-handed" or "four-footed" vertebrates; but for the reason that these terms did not include all the representatives of the Class, they have gradually come to be abandoned. It is evident that under such terms the bats would be excluded, as well as such undoubted mammals as man and the whales. *Homo* is a bipedal vertebrate, and the whales are great marine mammals; both bring forth their young alive and nurse them at the breast. They are also mammalian in their anatomical structure. It was the famous Swedish naturalist Linnæus who invented the name Mammalia, and its derivatives have all naturally followed. It is now in common use among English-speaking zoölogists, and the French biologists have it as *Mammifères*. Finally, it is as well to note that the name "quadruped" would include many reptiles and batrachians, and perhaps other forms; it is therefore objectionable.

As has been said, then, we employ the term Mammalia to include all existing mammals, and such extinct ones as undoubtedly belonged to this, the highest Class of the vertebrate sub-kingdom, and by far the most important one. When we come to consider only those mammals still existing on the Earth, as forming the Class Mammalia as it now exists, its limits as a class are perfectly well defined and universally recognized by biologists.

As already stated, a modern mammal is primarily characterized by the possession of mammæ or breasts, or, more strictly speaking, mammary glands with teats. These are rudimentary in the males, but highly developed in the females, becoming functional after pregnancy, when they secrete milk for the young. To this last the four existing representatives of the *Ornithodelphia* of the Australian region form exceptions, as it is now known that both the Spiny Ant-eaters (*Echidnidæ*) and the "Water-Moles" or Duckbills (*Ornithorhynchidæ*) lay eggs from which the young come forth, and that the mammary glands in the females of these low forms of mammals are extremely rudimentary in structure. It goes almost without the saying that all mammals possess, as a component part of the skeleton, a spinal column formed of a series of free bones called *vertebræ*. In this they agree with all the other classes of the Vertebrata, as birds, reptiles, fish, and others. They also possess in their anatomical structure all the other characteristics common to the vertebrate division of the animal kingdom generally. In common with birds, mammals are warm-blooded animals, and possess a heart with four cavities and a complete, double circulation. They differ from reptiles in both of these particulars, and from both birds and reptiles in that the red corpuscles of the blood are almost without exception circular in outline and nucleated.

In mammals the lungs are freely suspended within the cavity of the chest, which cavity is separated from the abdominal one by a muscular partition known as the diaphragm. They have a more or less abundant growth of hair, an outgrowth from the skin. A few scattered hairs have even been discovered in the case of whales, and in no mammal do we ever find the skin clothed with feathers. In no stage of their development do mammals ever possess external gills or branchiæ, though they agree with both reptiles and birds in the possession

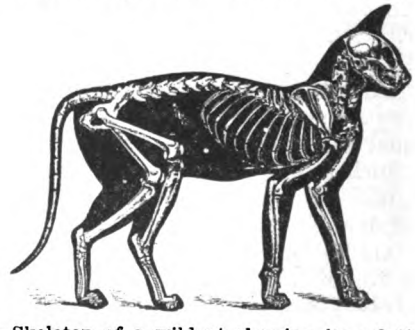

FIG. 2.—Skeleton of a wildcat showing its relations to the external form. (By the Author after Mivart.)

of an amnion and allantois during their early stages.

The aortic arch or main arterial vessel springing from the heart is single, and all mammals have certain structures, parts of the brain and central nerv-

ous system, highly developed; while the vocal organ, in the form of a complete larynx, is at the upper end of the trachea, being the reverse of what it is in birds,—they having a syrinx at the lower extremity of the windpipe, which is largely instru-

mental in the production of their notes and songs. In mammals, again, the upper vertebra (atlas) of the spinal column articulates with the skull by means of an articulate facet on either side—a pair of condyles. There is but a single median condyle in birds, reptiles, and other vertebrate forms. No mammal has more than two pairs of limbs, and these are, in the vast majority of species, completely developed and adapted to terrestrial locomotion. In whales the posterior or pelvic pair of limbs are very rudimentary and concealed within the body of the animal; in bats the anterior or pectoral pair are greatly modified to subserve the faculty of flight. Fossorial mammals, as moles and others, also have the anterior pair adapted to the requirements of animals that are constantly burrowing in the earth, and spend most of their time beneath the surface of the ground. Seals have their limbs modified as paddles, as do other pelagic forms; while some arboreal mammals have their limbs modified to meet the life they lead among the branches of the trees where they live, rarely descending to the ground. The pectoral, or anterior pair or fore limbs, are invariably present in mammals, and, in one way or another, fully functional.

There are no very close connecting links between existing Mammalia and any other group of existing vertebrates, such as birds and reptiles. This, as has already been said, renders the limital definition of the group quite perfect; but this was by no means the case in the early ancestry of mammals. The interval between them and vertebrates of other main Classes becomes less and less perfectly defined as we pass back into the geologic history of the mammalia. This is true of all existing animal groups. A good instance of it is seen in birds and in vertebrates that are nothing more nor less than greatly modified reptiles, which every particle of fossil material in our hand goes toward proving most conclusively. Birds and reptiles sprang from a common ancestry, and their earliest ancestral stock known to us is reptiliform. At a more remote period they were derived from more and more primitive types and forms, until the two branches merged into each other at the dawn of animal life upon Earth. Mammals have a similar history and origin. At no period of time has any mammal, from man to the lowest mammalian type that has ever existed, had any other origin than through a more or less perfect physiological union of the sexes and fecundation by the male. It matters not whether the birth is from an egg, as in the *Ornithorhynchus*, or a viviparous one, as in man and monkeys; the fact remains the same, for no mammal, at any time, has ever been specially created and endowed with the structure and attributes it now possesses. Every individual mammal comes down along a definite line of descent, and has had its ancestry. As we pass back into time, these lineal descendants depart in form and structure more and more from the present existing types or species, and become more and more like the primitive forms. Sometimes the line of descent may be a little bent, one way or another, due to definite causes; still, thousands upon thousands of fossil remains, from all parts of the known world, support this law of evolutionary origin of mammals and other animals on the Earth.

Touching these and other points, the late Sir William Henry Flower of England has said that "In the gradual order of evolution of living beings, mammals taken altogether are certainly the highest in organization, as they were probably the last to appear on the earth's surface, though this must be said with some reservation, pending further knowl-

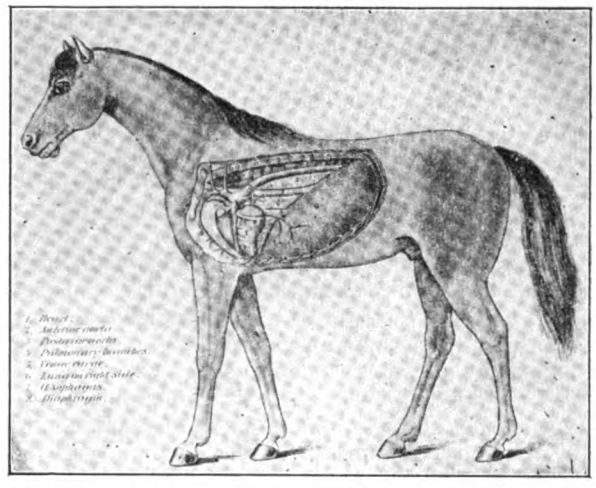

FIG. 4.—Anatomy of Horse; interior of chest, showing position of heart and diaphragm. Photo by the author. Haines del. after Colin. 1, heart; 2, anterior aorta; 3, posterior aorta; 4, pulmonary branches; 5, venæ cavæ; 6, lung on right side; 7, œsophagus; 8, diaphragm.

edge of the early history of the class birds. But, as in speaking of all other large and greatly differentiated groups, the expression must not be understood in too limited a sense. The tendency to gradual perfection for their particular station in

life, which all groups manifest, leads to various lines of specialization, or divergence from the common or general type, which may or may not take the direction of elevation. A too complex and sensitive condition of organization may in some circumstances of life be disadvantageous, and modification may then take place in a retrograde direction. In mammals as in other classes there are low forms as well as high forms; but by any tests that can be applied, especially those based on the state of development of the central nervous system, it will be seen that the average exceeds the average of any other class; that many species of this class far excel those of any other in perfection of structure, and that it contains one form which is unquestionably the culminating point yet arrived at among organized beings."

In speaking of the history of the Mammalia in past times, the same distinguished writer has said that "such knowledge as we yet possess of the history of mammals in past times is of very recent growth, and is still extremely incomplete. The very rapid advances which have been made in the last few years, especially in consequence of the explorations of rich fossilferous beds in North America, have not only completely changed the present prospect of the science, but give such promise for the future that any sketch, which we might now attempt of this branch of the subject, could only be regarded as representing a transient phase of knowledge." (1883).

About the time that this was published, the late Joseph Le Conte remarked in his *Elements of Geology* that "One of the most noteworthy facts connected with the first mammals is the apparent suddenness of their appearance in great numbers. We have already seen small marsupials quite abundant in the Mesozoic, but no trace of *true* mammals. In fact, the existence of these would seem to be incompatible with the reign of the huge reptiles. But, with the opening of the Eocene, the earth seems to swarm with mammals. And this is true not only in Europe, where the unconformity of strata indicates a lost interval at this point of the history, but also on the Western Plains and Rocky Mountain region, where the Cretaceous seems to graduate insensibly into the Tertiary. . . .

"True placental mammals not only appear suddenly and in great numbers, but of nearly all orders, even the highest except man, viz., monkeys. These, however, are not typical monkeys, but lemurs, which may be regarded as a generalized form, connecting monkeys with other orders." (p. 517.)

Even before these lines were written by Doctor Le Conte, an enormous amount of fossil material, representing the ancestors of many mammals, had been collected, examined and reported upon by palæontologists. Then, too, a great deal had been accomplished in Europe and in other parts of the world. In American deposits have been found the fossil remains of many of the extinct ancestral forms of the great order of Pachyderms; they represent Proboscidians and various species of Rhinoceros and Hippopotamus. Through the discovery of such fossils as are represented by the *Coryphodontidæ*, much light was thrown upon the common ancestral stock of the generalized form of Herbivores, and the even more generalized Carnivores. The former were generally five-toed Ungulates resembling tapirs, while the latter approached nearer the bears than any other modern group of mammals. The remarkable group of the *Dinocerata* is now pretty generally known and need not be described here. The almost complete ancestry of such animals as horses, camels, and others, had been worked out, as well as the line of descent of the Cats (*Felidæ*) and other interesting families and orders. In speaking of the Tertiary period, Le Conte has said that from "the earliest and most generalized types, therefore, to the present specialized types, the principal changes have been, first, from plantigrade to digitigrade, second, from short-footed digitigrade to long-footed digitigrade, *i.e. increasing elevation of the heel;* third, from five toes to one toe in the Horse, or two toes in the Ruminants, and fourth, from simple omnivorous molars to the complex herbivorous millstones of the Horse and Ox.

"The change from plantigrade to digitigrade, with increasing elevation of the heel, when taken in connection with the increasing size of the brain, and therefore presumably with increasing brain-power, shows a gradual improvement of structure adapted for speed and activity, and a *pari-passu* increase of nervous and muscular energy necessary to work the improved structure."

Le Conte says, moreover, that the mammalian fauna of the Quarternary, which follows the Tertiary, "is almost wholly peculiar.

"It differs greatly from the Tertiary fauna preceding, and the present fauna succeeding. The species are, moreover, very numerous, and many of them of extraordinary size; for it is the culmination of the mammalian age."

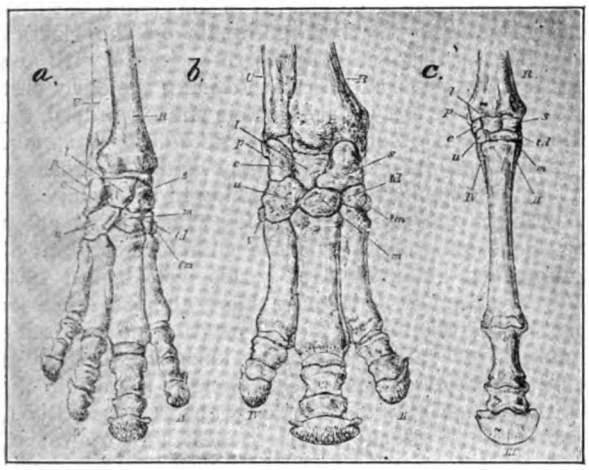

FIG. 7.—Bones of manus (*a*) of Tapir (*Tapirus indicus*) 1/5; (*b*) of rhinoceros (*Rhinoceros sumatrensis*) 1/5; (*c*) of horse (*Equus caballus*) ⅛. II and IV rudimentary metacarpals. During the Quarternary the fossil remains have principally been found in caverns, during that or those times the animals were floated onto beaches and terraces, were sunk in marshes and bogs, and finally were preserved in frozen soils and in the ice cliffs. The principal mammals, among a host of others, were various huge creatures of the elephant type (Mammoth), great deer and elk, lion, bears, enormous sabre-toothed tigers, ponderous edentates (*Megalonyx*, etc.), armadillos, and big pachyderms. Man also appeared in abundant evidence among the other mammals, along with which he had risen from the tertiary and earlier ages in geologic history.

In writing about the history of any group of animals in time—the world-time—I usually speak of the *ascent* rather than the *descent* of the particular group in question. That is, all animals have, in the history of the Earth, *ascended* from the most primitive forms imaginable. Mammals have formed no exception to this rule, and man, which is only another name for another family of mammals, stands in the same case. Every individual mammal now living on the Earth has sprung from a pair of parents—parents more or less like their progeny, yet, in a specific sense, different. Passing backward through the ages, these minute, fractional differences have always occurred, so that in enormous, unthinkable ages of time—which ages may be considered as constituting the world's history—it has become possible to appreciate the significance of these changes. They have constituted an evolution of forms, which now covers a vast and far-reaching history, but which it will not be the province of the present work to deal with further here.

Be it remembered, however, that the present existing game mammals of North America are but the now-living representatives of a long, long line of ancestry. As we trace any one of them back by the fossil remains of any such of their ancestors as we have been so fortunate as to have discovered, we find that, the further we go back into time, the more and more do the various forms depart in all particulars from the now existing species. This is indicated by the geological horizons in which the fossil remains are found. Not only this, but the further we trace any species or genus of mammals back, the nearer and nearer they approach some other great group in time, and the latter in turn, still further back in the world's history, converged toward some other group. Take such "Cats," for example, as we now have in our fauna; what has just been pointed out applies to them. At present they nearly all belong, such as the jaguars and the cougars, to the genus *Felis*, while the lynxes are arrayed in the genus *Lynx*. For many generations back all of their ancestors belong to these two genera, although these differ more and more the further back they are traced, until we come to meet with some—only a very few at first—that have become so different that, were they in existence to-day, we could not place them with the modern Cats in the genus *Felis*. Among the former we find such types as the nearly cosmopolitan and ponderous Sabre-toothed Tigers (*Smilodon*) of quarternary times, and a great many other Cats, the fossil remains of which have been discovered. The reader who desires to follow this particular group (*Felis*) further, and look into the wonderfully interesting history of the origin and evolution of the *Felidæ*, can do no better than read the many papers on the subject by such eminent writers as the late Professor Cope, Burmeister, Mivart, Owen, Cantley, Falconer, De Blainville, Gervais, Leidy, Filhol, and not a few others who have paid attention to this subject.

But in North America alone we have found fossil remains representing hundreds of other species of mammals. In tertiary times these are seen to be

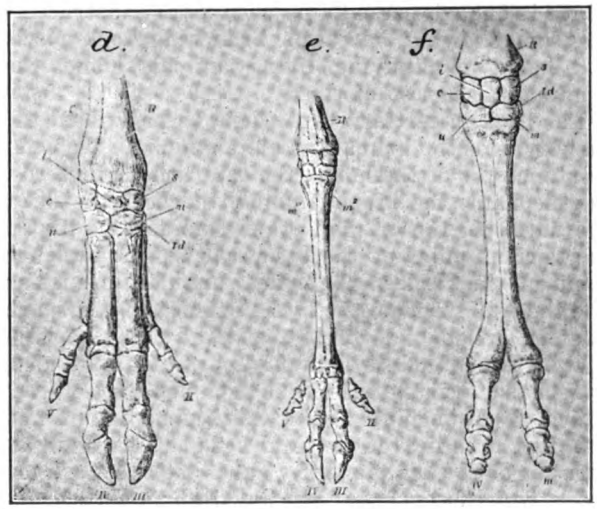

FIG. 8.—Bones of manus (*d*) of pig (*Sus scrofa*), ⅛; (*e*) of red deer (*Cervus elaphas*), 1/7; (*f*) of camel (*Camelas bactrianus*), ⅛. Lettering the same as in Fig. 7. (After Flower.)

nearly all connecting types, belonging to two generalized series, which Cope designated as the Bunotheria and the Amblypoda. From the former, by differentiation, there arose the carnivorous mammals, the insectivorous, the quadrumana, and the

like; while from the latter came the Ungulata with its various family groups.

It was the great French savant, Cuvier, who divided all the ungulate mammals into two great orders, which he named the Pachyderms and the Ruminants. "The Pachyderms," says Le Conte, "are a heterogeneous order, but the Ruminants have been regarded as one of the most distinct of all mammalian orders. Their horns in pairs, their hoofs in pairs, absence of upper front teeth, complex stomachs, and the habit of rumination, differentiated them widely from all other animals." But Prof. Owen showed that this distinction, so clear in zoölogy, was untenable in palæontology. He found, in studying extinct Ungulates, that another distinction, viz., foot-structure, was more fundamental and persistent. He therefore divided all Ungulates into *Perissodactyls* (odd-toed) and *Artiodactyls* (even-toed). A Perissodactyl may have five toes, as in the Coryphodon and the Elephant; or three toes, as in the Palæothere, the Rhinoceros and Tapir; or one toe, as in the Horse. The Artiodactyls always have their toes in pairs; there may be only two toes, as in Anoplothere and in Ruminants; or four, as in the Hog and the Hippopotamus. Owen, indeed, made the Elephant, Mastodon, etc., a distinct order under the name of Proboscidians; but these are probably best regarded as a very distinct offshoot or suborder of the Perissodactyls.

"Now, in earliest tertiary times the Perissodactyls and Artiodactyls already had diverged from a common stock, probably something like the Coryphodontidæ, although these were doubtless more nearly allied to the Perissodactyls. Each of the primary branches then divided and again divided, until the extreme branch in one direction became the Horse, and the extreme branch in the other direction the Ox." (*Elements of Geology*, pp. 531, 532).

Professor Le Conte, in the work from which the above is quoted, presents us with a very instructive diagram showing how this branching took place, and how "by studying living animals alone, the Ruminants seem so distinct."

Far back in tertiary time, then, there existed the early type of the primal ungulate mammal, the common ancestor of the horse, the tapir, the rhinoceros, the elephant, the hippopotamus, the hog, the deer, the antelope, the ox, and other ruminants with all the various allies of these several types. As time went on, the stock of the primal ungulate branched, and the Amblypoda came into existence. One branch was the artiodactyle branch and the other perissodactyl. The artiodactyle in due course again divided, one branch giving rise to a common stock from which, by branching again, the hippopotamus and the hog families were produced; while another, turning off rather abruptly, gave rise to a common stock, which branches in a tripartite manner, throwing off the deer family, the antelopes, and the bovine animals—the ruminant group of modern or present-day mammals. The other branch of the Amblypoda or the perissodactyl branch, in due course again divided, one branch giving rise to a common stock, from which, on the one hand, the proboscidians were differentiated, while on the other the ancestral stock of the horses on one line, and the tapirs and rhinoceroses on the other, were the groups that eventually evolved, and they are with us at the present time. So, according to this, our deer, antelope, and ox groups all sprang from a common ancestor, which arose from the artiodactyl stock of the amblypoda, one of the two branches of the primal ungulate stock of the tertiary period.

As to how many years ago it is that mammals first came into being as *true* mammals on the Earth's surface, it is quite impossible to estimate with any accuracy. They were ushered in during the early part of the Cenozoic era (early Eocene time); indeed, the Cenozoic era is often known as the *age of mammals*. It is divided into the Tertiary and Quarternary periods. The Quarternary is followed by *the present* or "Recent age" (Psychozoic). The Glacial epoch was the earliest epoch of the Quarternary, and it "commenced about 240,000 years ago, lasted 160,000 years, and 80,000 years have elapsed since its close." (Le Conte). Many of the now-existing mammals, or rather the same species, were to be found in existence then. Geologically speaking, the cutting of the Niagara Gorge by the Niagara River, is an event of recent time; it is still in operation, and a long way from being completed. It is going on at the rate of about one foot per annum, and Mr. Lyell, who has carefully computed it, states that thus far it has required 36,000 years. But this, as a time-matter, is of very small moment—absolutely insignificant as compared with the enormous lapse of eras and periods since the *beginning of the Tertiary*. Powell and Dutton have estimated that the average erosion over the whole of the Colorado Plateau region amounts to 6,500 feet, and this does not include the forming of the Colorado Canyon by the Colorado River, a cutting of 11,000 feet. Now take such a river as the Mississippi, one of average erosive power, as the gauge for our measurement, the rate of continental erosion, *at the present time*, is about *one foot in five thousand years*. To cut 6,000 feet would require 30,000,000 years. The enormous mass eroded on the Colorado Plateau has been carried off since the *middle* of the Tertiary time, and, as has just been said, the average thickness of the Earth's crust there is about 6,500 feet. The first mammals may have then appeared on the scene in this world about forty or fifty millions of years ago. It is at least ten thousand years since man, as *man*, came into being; but, as in the case with all other mammals, the evolution has been *extremely gradual*. No one can possibly conjecture what kind of animals there will be living in the world at the end of another million of years, to say nothing of fifty millions. The present mammalian fauna of the world will have been extinct for ages. No species now in existence will be in existence *then*,—that is, if that time ever arrives for the world. There may be no life on the Earth at all, the entire globe having become as cold and as dead as a moon. Only seventy-five or a hundred years ago our western prairies absolutely swarmed with bison, a large and conspicuous mammal; to-day there are not one thousand of them in existence. In a few generations more not an elk, nor a prong-horn antelope, nor a cougar, nor a grizzly bear, nor a dozen such forms will be in existence anywhere. All exterminated! Known only by their remains in museums, and what we are saying about them in present-day literature.

Quite apart from the question of the origin and evolution of mammals on the Earth, though in a way related to it, there is to be considered another and one of marked importance, and this is the geographical distribution of mammals. In studying the evolution of the Mammalia from our earliest knowledge of them to the present time, we resort to the consideration of all the fossil remains in our possession, and this material is duly compared with all we have learned about the species now existing. New geographical distribution, or, as it is also termed, Zoögeography, on the other hand treats of the dispersion of the various living forms over the land and water areas of the Earth, be they of plant or animal life. So far as possible, this takes into consideration geologic, as well as present time, and if mammals be the class engaging our attention, we designate the study of Zoögeography of the mammalia, and so on for all the other groups. Our knowledge of the geographical distribution of the earliest known mammals is extremely meagre. This is due to the fragmentary nature of the material thus far discovered, for it is clear that we can only depend upon fossil remains for anything we may hope to learn about it.

As we approach quarternary time, however, and pass in review what we have discovered in regard to tertiary mammals, the data become far more extensive, and our knowledge of the distribution of extinct mammals over the Earth and in the waters thereof considerably improves and widens, but still remains quite insignificant as compared with what we know of the zoögeography of existing species of mammals. The reason for this is very evident. Thousands upon thousands of species of mammals have lived through entire geologic times and become utterly extinct, and of them we have as yet discovered none of their fossil remains. Then such fossil mammals as we have come across have been found only in particular localities, thus giving us but little knowledge of the areas over which they roamed at the time they flourished, their comparative numbers, or the times of their coming into being, or when they died out. For existing faunæ, however, the state of things is entirely different; for every year that passes we become more and more familiar with the exact regional limits constituting the present habitat of any particular mammal now known to us, be that mammal a terrestrial species or an aquatic one. Knowledge of this character at the present time is very extensive, and, to a remarkable degree, very accurate; it forms an important chapter in the biology of mammals, and further on in the present article will be applied to our studies of the game mammals of this country.

To a certain extent, the time any particular species of mammal appeared in the world's history, and what its geographical range was at any time during its life's history, are related questions, the one bearing upon the other. If such a thing ever happened in the history of the Class that only one individual of any particular species had come into existence and perished without leaving any descendants, the questions of the geographical distribution of that individual and of the time at which it lived would be coincidental ones. The same would apply to the last individual of a species or a race in the present fauna. For example, suppose all the beavers (*Castor canadensis*) in captivity had died out, and there remained in existence but one single specimen in the wild state. Were it to die tomorrow on the shores of Hudson's Bay, it could only be said of it that it was a mammal of the Psychozoic age, and that its geographical range had become restricted to the very identical point where the animal had expired and the race become extinct. Therefore it is clear that, during the existence of any particular species of mammal, the geographical distribution of that species may never be fixed. From one cause or another the species may be rapidly extending the limits of its range, or, for other causes, that range may be becoming restricted and the species on the road toward extermination or extinction. Some few of the causes for these fluctuations in the status of various species of mammals in regard to their geographical distribution will be touched upon further on.

It is possible that, in former times, the buffalo (*Bison americanus*) had a geographical distribution extending over the entire territory now known as the United States and parts of British America and Mexico. The animal now is at the point of extinction in the wild state, and its geographical distribution is restricted to a few points in the Yellowstone Park and in the Pan Handle of Texas. The cause for this is too well known to warrant the space for discussion here.

In quarternary times, the age that just preceded the present one, the geographical distribution of the main families of mammals was quite similiar to what we find in our now-existing fauna; but the animals were of gigantic proportions, and the species and numbers far more abundant. There were many other species, too, that died out in the quarternary and left no descendants. We have no idea what they appeared like in life, while in some other cases we have.

Now the mammals of the tertiary in North America were entirely different from the animals of the present-day or existing fauna, although the latter are their descendants. It is a good many millions of years ago since the miocene time of the tertiary; but during that age there no doubt existed a mammal of which we now possess the fossil remains, and which we call the *Oreodon*. It was a remarkable animal, having affinities with the camel, the deer, and the hog. Notwithstanding the enormous, almost inconceivable, lapse of time since it roamed over this country, with the physical topography it had in those days, we can with certainty state now that a large part of its range or geographical distribution included all that portion of the Continent now known as extending from Nebraska to Oregon. Its fossil remains have been discovered in a sufficient number of places in this region to convince us of the truth of this, though we cannot, of course, state with certainty what the exact limits of its range were.

The Mammalia are especially serviceable for our purposes in working out the various problems presented us in our studies of geographical distribution. The eminent British naturalist, Wallace, employed them with marked success in this line of investigation, and he was one of the most distinguished of zoögeographers then living. As Sir William H. Flower has said, the reason they can be employed

with such advantage is, that "owing to the comparatively limited methods of locomotion or transport which most of them possess, the area of distribution of each species is more definite and restricted than in some other classes."

It is evident that mammals may, according to their principal methods of locomotion, be divided into three main groups, as effecting their distribution over the surface of the Earth. These groups are first, aërial, second, aquatic, and third, terrestrial mammals. The bats are the only aërial mammals we have, while the chief aquatic ones are the seals, the sirenians, and the cetaceans, as the whales, porpoises, and their allies. A discussion of these two groups need not detain us here, as none of those mammals will be described in the present article, and we can demonstrate all that is necessary in regard to geographical distribution here from a consideration of the last group or the terrestrial mammals.

"One of the most important facts connected with present distribution of terrestrial mammals," says Flower, "but one of which the cause is sufficiently obvious, is their entire absence, except where introduced by the direct agency of man, from all oceanic islands, including even the great New Zealand group. Another, equally striking, but less easily explained, is the very marked isolation as regards its mammalian fauna of the Australian region of zoölogists. When once the narrow neutral ground on the border line between this and the Oriental region is passed, there is not found, notwithstanding the vast extent of land it comprises, a single indigenous placental or monodelphous mammal, except a few species of a single family (*Muridæ*) (Rats and Mice) of the very wide-spread order *Rodentia*—the Wild Dog or Dingo having been in all probability introduced."

It is a well-known fact, on the other hand, that the Monotremes, as the Duckbills, Echidnas, and the Marsupials, are almost entirely confined to this region—the American opossums forming the only exception.

The placental mammals are distributed more or less generally throughout the other zoölogical regions of the Earth, "and in many cases form valuable indications by which the natural boundaries of these divisions have been traced. Many anomalies, otherwise inexplicable in the present range of families and species, have been cleared up by the study of their distribution in former geological epochs, a subject in relation to which the present facts of distribution should always be studied. There are few lines of evidence so conclusive as this in favor of the existing species being modified lineal descendants of those which have lived in previous times upon the Earth." (Flower.)

Coming back again to our direct consideration of the significance and the importance of zoögeography, we find it primarily to be a scheme by means of which we can classify our knowledge of animal distribution, and in an orderly manner present it to the mind, so that it can be easily appreciated. As pointed out in my "Lectures on Biology," delivered in Washington, D. C., a number of years ago, many scientists have devoted years of study to this subject alone, and among them we must not neglect to mention, in addition to Mr. Wallace already referred to, the names of Buffon, the eminent French biologist, Agassiz, Allen, Gill, of this country, Sclater of London, and Alexander von Humboldt.

For the better appreciation of the data of distribution of existing and extinct animals and plants, naturalists have divided the land and water areas of the world into certain divisions according to certain laws and circumstances. Recently American biologists have thus divided the American Continent; in the present connection, however, it will meet my purpose, as it has upon former occasions, to adopt the views so ably presented by Mr. Wallace. As in the case of other departments of science, zoögeography has grown up from early and crude notions of its principles to its now largely elaborated state. American zoölogists, as a rule, divide the land and water areas of the face of the Earth into divisions in chief, which they term "realms;" while our British confrères give the name "regions" to those areas.

Now, as has already been pointed out above, it is a well-known fact, that certain mammals are practically confined to the dry land, while others are aërial or aquatic by nature. There is, however, still another factor that enters into the question of distribution not mentioned. In any given locality, where the land area rises as mountains into unusual altitudes, it is to be observed that, in any such given locality, it frequently happens that the mammalian fauna of the bases of such elevations is quite different from what we find at the summits or peaks, and, moreover, the species gradually change as we ascend or descend. For example, in some parts of the Big Horn Mountains or mountain region, one will meet with antelope in the foot-hills, grizzly bear half way up, and pikas on top, and similar instances hold good all over the world. Not only do differences of latitude and longitude, differences of climate, and depressions and elevations in the land areas, influence the kinds of mammals and other forms found in those various parts of the world, or in any particular country, but the diversity in the physical geography of the Earth's surface, as a whole, is another powerful factor in determining faunal limits. Plains may encourage extended migration, as hills, mountains, large rivers, and seas may check the same. The abundance, absence, or scarcity of certain foods over certain areas also have an influence. In many cases the faunal limits can be but loosely defined, as any faunal district may almost imperceptibly merge into any one of its adjoining ones; but certain surface contours may often, on the other hand, sharply define some of the boundaries, and animals of the contiguous areas not pass over the line. Some species—and it applies to the mammals of this country—may range through several faunal areas; others are, perhaps, never found beyond some quite limited locality—these several restrictions and diffusions nearly always being due to assignable natural causes. Where certain species arrive at their maximum of abundance, it is generally supposed to indicate the area of the origination of that species. This last, however, is by no means always true.

Soils also play their part, and it will be clear that the fauna of the extensive marshy districts are sure to be quite unlike the fauna of a great desert; indeed, in the case of the latter, it has led an emi-

nent authority to say that "deserts may act much like inland seas to separate the animals of the adjoining, more fertile, tracts, and they afford dwelling-places for animals which are incapable of living elsewhere. Desert faunæ have a general *facies* the world over, though the original elements, out of which the faunæ have been made up, may radically differ."

In so far as mammals are concerned, our western American deserts often offer fine examples of this law. Our government naturalists have taken many species of small mammals in the desert regions of the United States found nowhere else in this country or in the world.

Although a great ocean, such as the Pacific or the Atlantic, forms almost a positive barrier to the spread of the land animals of its opposite coasts, which are invariably quite distinct, yet, at the same time, within its own self, the great ocean currents form means of dispersal of prime importance for many land animals and the vast majority of marine forms. Again, as we have already pointed out, climate, in most cases, is a positive barrier to the spread of animals in many directions, whereas the alternation of the seasons, and even the severity and mildness of the summers and winters, powerfully urge many animals to migrate, and thus, for the time being at least, to pass beyond either their local or general faunal areas. Migrations from such causes in the main, however, take place within the boundary of any faunal region where they occur. A familiar example of this is our own United States vernal and autumnal migration of birds, which takes place every year, and that for the entire width and breadth of the Continent. The enormous known migrations of lemmings and grey squirrels are probably influenced by other causes.

As another means of dispersal of animals—though one having little or no effect upon mammals of the present time in this country—we have those various movements which take place in the atmosphere itself; and it has been noted that the trade winds, hurricanes and cyclones, or even minor whirlwinds, do much sometimes toward scattering the lighter forms of animal life, as well as the seeds of many plants; by such means new organisms are often transported to distant areas, to which they were formerly unknown. In any special case, should the environment prove compatible to a species thus violently introduced, that species may become established and thrive in the new region, or it may, the reverse holding true, become gradually extinct, or even perish at once.

Quite a number of artificial means, introduced by man himself, have, from time to time, acted as factors, in either favoring the dispersal of certain animals or tending to restrict them to certain localities—bridging large streams; the transportation of many of the smaller forms in steamers, grain cars, trains, and other modes of conveyance; the joining of large bodies of water by means of the opening of artificial canals, and finally, even the construction of country roads, have all had their influence along the line indicated.

Already reference has been made to the dispersal and rearrangement of faunæ and floræ in past ages of the world, and they were powerfully affected by geologic changes, as, for example, the effects produced by the glacial period as a whole, as well as those profounder changes: the upheavals, depressions and submergences of continental margins and areas. It must be borne well in mind that, at the present time, the faunæ, which of course include all the mammalian faunæ of the various zoögeographic regions, are continuously, but gradually, undergoing many changes, brought about by the extermination of some forms, by the slow development of new species, and by the gradual physical changes of the Earth characteristic of the present epoch.

To sum them up, we may say in the words of Huxley: "It has been discovered by careful comparison of local faunæ and floræ that certain areas of the Earth's surface are inhabited by groups of animals and plants which are not found elsewhere, and which thus characterize each of these areas."

We are now in position to return to the naming of those areas, and, as I have already said,. the views of Mr. Wallace will be the ones set forth to exemplify the manner in which naturalists have divided the face of the Earth into regions for the purposes already designated above. There are doubtless later views than his; but in the main, the same arrangement obtains in them all, while the boundaries may change from time to time as our biological knowledge, as a whole, widens.

It was in 1876 that Wallace published the work containing his scheme; he then recognized six primary zoögeographical regions of the globe, and subdivided them as follows:

I. Palæarctic region, with four subregions: (1) North Europe; (2) Mediterranean, or South Europe; (3) Siberia; (4) Manchuria, or Japan.
II. Ethiopian region, with four subregions: (1) East Africa; (2) West Africa; (3) South Africa; (4) Madagascar.
III. Oriental region, with four subregions: (1) Hindoostan, or Central India; (2) Ceylon; (3) Indo-China, or Himalayas; (4) Indo-Malaya.
IV. Australian region, with four subregions: (1) Austro-Malaya; (2) Australia; (3) Polynesia; (4) New Zealand.
V. Neotropical region, with four subregions: (1) Chili, or South Temperate America; (2) Brazil; (3) Mexico, or Tropical North America; (4) Antilles.
VI. Nearctic region, with four subregions: (1) California; (2) Rock Mountains; (3) Alleghanies, or East United States; (4) Canada.

As has already been intimated, these regions are practically independent of the question of the marine distribution of animals. But the principles which apply to zoöoceanic areas and regions are, in the main, almost identical with those laws which govern the occurrence of life-forms in the terrestrial zoögeographical divisions. So that, for our present purpose, they need not be especially discussed here.

With respect to the terrestrial divisions just given, and using Mr. Wallace's own words, we are to note that the "I. Palæarctic Region, which includes all Europe to the Azores and Iceland; all temperate Asia from the high Himalayas and west of the Indies, with Japan, and China from Ningpo and to the north of the watershed of the Yang-Tse-Kiang; also North Africa and Arabia, to about the

line of the tropic of Cancer. This may be popularly called the European region, Europe being the richest and most varied portion of it and containing representatives of all the more important types; but it must not be forgotten that the region includes a much larger area in Asia, and that there are many peculiar North Asiatic animals.

"II. The Ethiopian Region, which includes all Africa south of the tropic of Cancer, as well as part of Arabia, with Madagascar and the adjacent islands. It may be popularly termed the African region.

"III. The Oriental Region, which is comparatively small, including India and Ceylon, the Indo-Chinese countries, and southern China, and the Malay Archipelago as far as the Philippines, Borneo, and Java. It may be popularly called the South Asiatic or Indian region.

"IV. The Australian Region, which is composed of the remainder of the Malay Archipelago, Australia, New Zealand, and all the tropical islands of the Pacific, as far east as the Marquesas and the low Archipelago.

"V. The Neotropical Region, which comprises the whole of South America and the adjacent islands, the West Indies or Antilles, and the tropical parts of Central America and Mexico. It may be called the South American Region.

"VI. The Nearctic Region, which consists of all temperate and arctic North America, with Greenland, and is thus well described as the North American Region."

It is hardly necessary to point out here that extensive areas of the Palæarctic, Nearctic, and other regions are under a high state of cultivation, and that much of the area they cover is thickly populated. In consequence of these two facts, extermination, in times past, has been the fate of many of its mammalia, and this process is at present going on more rapidly than ever. It has thinned the ranks of animal life within the boundaries of those regions to such an extent that, notwithstanding the extensiveness of one of them—the Palæarctic—it ranks at present below the smaller Old and New World regions of the tropics in the richness of its mammalian fauna. Some of the forms of the Palæarctic Region, however, are quite peculiar, while others are highly characteristic. There are camels and a half-dozen different genera of deer; a genus of dogs of the family *Canidæ* occurs, and a great variety of the rodentia abound, as rats, mice, squirrels, hares, and their kind. Seven genera of ruminants fall within the limits of this region, all of the family *Bovidæ;* weasels and pandas are also characteristic. Upon its northern coasts are found seals, and the land carnivora are well represented in the wildcats, the wolves, foxes, and bears. In other parts wild horses and asses exist, the latter being abundant in Asia.

Passing to the Ethiopian Region, which includes in the main Africa and the great island of Madagascar, we are struck at once with the marked differences in its mammalian fauna as compared with what we found in the Palæarctic Region. Madagascar and the Mascarene Islands are especially remarkable, and in the case of the first-mentioned we find many characteristic small mammals not found on the African Continent, while it lacks all the large carnivora, the apes, giraffes, elephants, antelopes, and others which are found there. Through the recent explorations of Sir Harry Johnston, some large and very remarkable mammals have been added to this region, such as a new giraffe and an ant-bear; but above all else the extraordinary mammal the *Okapia johnstoni.* Even Wallace admitted, thirty years ago, that "the African Continent is preëminently the country of large mammalia. It possesses an abundance of elephants, rhinoceroses of several species, giraffes (now peculiar to it), gorillas and baboons, the largest of the ape tribe, a host of large and remarkable antelopes, the huge hippopotamus, several species of zebras, wild buffaloes, several remarkable forms of swine, and an abundance of lions, leopards, and hyenas—forming together an assemblage of large and highly organized animals such as occur nowhere else upon the globe. There are also many smaller, but remarkable forms."

And so it goes with the four remaining regions defined above, the Oriental, the Australian, the Neotropical, and the Nearctic. Each possesses its peculiar and characteristic forms of mammals, and each region its varying physical aspect. What has been said of the first two holds true, in principle, in all the others. In the present article, the mammals of the Nearctic interest us most, and particularly the game mammals; but, as their distribution in the United States will be touched upon further along, the subject will not be entered upon here. The main object of the present article has been to bring before the reader the salient principles of the question of animal distribution on the face of the Earth, both in the present and past ages of the world's history.

Australia of the Australian Region is especially characteristic, inasmuch as all the more ordinary forms of mammals are not found there, their room being taken by the varied group of the marsupials, of which there are five distinct families and many genera. *Echidna* and *Ornithorhynchus,* two other distinct families of most remarkable mammals, are also found on the Australian Continent.

As has been noted above, we thus see how it is that animal and plant life is distributed over the face of the globe according to certain natural laws, and that those distributions have varied during the past history of the Earth, owing to the varied application of the same laws, and to other circumstances. In short, there is, in the individual case of any existing animal or plant on the Earth, *a reason* for its being found over one area and not over another. There is a very good reason why the moose is found in Maine and not in Mexico or Africa, and why the Okapi (*Okapia johnstoni*) is found in the heart of the latter country and not in the Rocky Mountains of North America, or in the forests of Australia. There is a very good reason why we find the sage brush (*Artemesia*) growing over our western plains and not over the barren tracts of Central Thibet, or why we find yucca flourishing in Mexico and not in Michigan—and so on for everything else that now lives on the Earth or ever has lived upon it.

Science has made very considerable progress toward the elucidation and demonstration of many of the laws to which reference has been made in this article; there still remains, however, in the grasp of the great unknown a vast store of facts not yet

brought to light, though the incessant investigation of the scientific researcher tends to pass them almost daily over to the realm of the known.

3356 EIGHTEENTH STREET, N. W.

THE THERAPY OF HYPERTHYROIDISM.

BY M. FORD MORRIS, JR., M.D.,

ATLANTA, GA.

INSTRUCTOR IN MEDICINE IN THE SCHOOL OF MEDICINE OF EMORY UNIVERSITY, VISITING PHYSICIAN TO THE ANTI-TUBERCULOSIS ASSOCIATION.

THE results of the non-surgical treatment of hyperthyroidism are most gratifying. Indeed, the majority of cases improve steadily, if the following plan of treatment is carried out. However, cures do not occur after several weeks' treatment, as usually the overcoming of the thyrotoxicosis is a matter of months. Sometimes, however, all medical measures fail to produce a cure, in which cases, after prolonged medical and *x*-ray treatment, surgical consideration is in order.

The essential part in the treatment of any disease is the eradication of the cause. This fact is especially true in hyperthyroidism. The cause of this condition is practically always toxemic or neurotic in origin. The source of the toxemia is usually an infection of the teeth, gums, tonsils, sinuses, gall-bladder, appendix, genitourinary tract, etc. The absorptions of toxins from the intestines in cases of intestinal stasis is a rather frequent cause. Syphilitic and tuberculous infection have been known to cause this condition. Therefore, the first therapeutic aim should be the discovery and removal of the source of toxemia. In cases of neurotic origin, which includes the rather numerous group of cases caused by fright plus trauma, diet and rest often effect a cure.

Certain hygienic measures are very useful in treating cases of hypersecretion of the thyroid. Good nursing; pleasant, quiet surroundings; warm, fresh air; two sponge baths daily, with plain or salt water, and the application of an ice bag to the thyroid and the heart, are all quite important. Absolute mental and physical rest is a necessity in the treatment of all but mild cases. The administration of much water, especially the imported Vichy, is of real value.

A suitable diet is most beneficial. Due to the excessive catabolism which occurs in these cases, a very nutritious diet is necessary to overcome this catabolic loss. This diet should consist of milk, buttermilk, cream, butter, cheese, eggs, plenty of bread, vegetables, soups, stewed fruits, cereals and a simple dessert, such as custard or rice pudding. All meats should be omitted, as Falta has found that a diet rich in proteins increases the thyroid secretion. On the other hand, Rudinger has found that a diet of carbohydrates tends to decrease the secretion of the thyroid. Alcohol, tea and coffee are also harmful. Vichy water administered in considerable quantities will neutralize with its sodium bicarbonate whatever phosphoric acid the blood may contain.

Medical measures constitute an important part of the treatment. These measures have for their object a diminution of thyroid secretion and an upbuilding of the body tissues. The best agents for the inhibition of thyroid activity are the vasoconstrictors, of which ergotin and the salicylates are probably the best. The neutral hydrobromide of quinine is also a favorite vasoconstrictor, as well as a stimulus to phagocytosis. Ergotin is given in one grain doses, three times daily. The quinine and the salicylate are given in about ten-grain doses, three times daily. Pituitary extract, adrenalin, scopolamine, and sparteine also constrict the vessels. Belladonna and hyoscyamus are of value when the tremor is troublesome. The bromides and chloral are helpful in relieving the nervousness and insomnia. Likewise, is Sumbul sedative worthwhile. Arsenic, in addition to its tonic effect, depresses the functions of the thyroid. Sodium phosphate, one dram to a glassful of warm water on retiring and arising is valuable, Kocher having found that thyroidectomized dogs become cachectic when sodium phosphate and magnesia are removed from their food. Another class of remedial agents is composed of those preparations which tend to restore to the nerve cells their functional constituents which have been more or less destroyed by the thyroid hormone. Lecithin in one teaspoonful doses, three times daily; thymus gland desiccated, grains five t.i.d., which contains phosphorus laden nucleins, and sweetbreads are the most important. In most cases, iron is of value. Several sera have been tried, some users finding them helpful, others finding them useless. Rogers and Beebe have prepared a serum by injecting into rabbits two proteids —a nucleoproteid and a thyreoglobulin—which serum has helped to counteract the toxemia. Another serum, obtained from thyroidless goats, has been praised. Antithyroidin, a German product, intended to neutralize the toxemia, is given in doses of 10 to 30 minims, once or twice daily. Rodagen, another German preparation, obtained by precipitation from the milk of thyroidectomized goats, has not been satisfactory. Likewise, thyroidectin, a reddish-brown powder precipitated from the blood of thyroidectomized sheep, was without effect.

The *x*-ray is a most excellent agent for depressing the excessive secretion of the thyroid. *X*-ray therapy is painless and easy; it leaves no scar; it causes no fatalities; when given in conjunction with proper medical treatment its results are excellent. The results of *x*-ray therapy are first, a feeling of improvement; later, the tremor diminishes, the tachycardia subsides, and there is a gain in weight. The question of dosage is most important and is to be determined by the skilled radiologist. Knox reminds us of several precautions to be taken in giving *x*-ray treatment, such as a careful estimation of dosage on each occasion, small doses given frequently, adequate filtration, the use of a penetrating ray and the use of secondary filters of leathers, loofah sponge, or any material which will absorb the soft rays. The thymus also should be *x*-rayed each time. Radium when given properly and in sufficiently large quantities will produce equally as good results as will the *x*-ray. Radium may succeed where *x*-rays fail, and vice versa. The technique may be faultily applied in both instances. When properly employed, radium gives rise to no reaction and produces excellent therapeutic results. Neither the *x*-rays nor radium should produce a dermatitis.

Injections of boiling water into the thyroid gland have been employed by Porter, resulting in some improvement. However, there have occurred three deaths from this proceedure. Watson has used injections of quinine and urea hydrochloride with encouraging results.

The surgical treatment has been purposely considered last, as this form of therapy, in the writer's opinion, should be resorted to only after the other lines of treatment referred to have failed. Surgical treatment has been the form of therapy most often used, probably because the average physician considers the statistics in the wrong light, e.g., the mortality from thyroid operations when done by Kocher and the Mayos is practically nothing—which means the deaths resulting from operation, and not the cures. Judd and Pemberton of the Mayo Clinic have shown that eight years after operation not more than 45 per cent. of cases are cured. It is evident, therefore, that the mortality rate of the average surgeon is 5 per cent. or more, and that the percentage of cures will hardly reach 30. When the other forms of treatment have failed, surgery is in order. When pressure symptoms develop or malignant degeneration of the thyroid occurs, surgical intervention is necessary. It seems that the chief rôle of surgery in the future therapy of hyperthyroidism will be in removing causes of the hypersecretion.

If, then, after finding and removing the cause or causes of this affection, we use proper hygienic, dietetic, medical and radio-therapeutic measures we will secure, without having to resort to thyroid surgery, a large proportion of cures.

1010 CANDLER BUILDING.

SOME FUNDAMENTAL PRINCIPLES UNDERLYING INTESTINAL AND RECTAL SURGERY.

BY JEROME M. LYNCH, M.D.,

NEW YORK.

SEVERAL recent studies have tended to indicate that human beings may be divided into groups or types according to their structural organization. Bean, who has studied racial types extensively in several parts of the world, has laid particular stress on the thin epithelial type and the robust connective tissue type. The first, or hyper-ontomorph, is a lank individual found to possess a long vertical stomach, short small intestine, and a long large intestine; the second, meso-ontomorph is fat and broad in general appearance with a large transverse stomach and a small intestine and short large intestine. Each type, Bean believes, may be prone to a particular disease which occurs only rarely in the other type.

Stockard, studying fron an entirely different standpoint, believes two chief types of individuals exist and that the one group differs from the other on account of having undergone its early postnatal development under a different complex of the internal secretions. The two types in the end correspond with Bean's—the hyper-ontomorph being an individual that has had a high physiological thyroid bringing about early differentation of organs and parts without excessive growth in size. The meso-ontomorph as a child had a low active thyroid, grew large in size, particularly in width, but its organ differentiation was slow. There are a number of correlated characters presented by individuals of characters shown by the other type.

Therefore a hyper-ontomorph, or high thyroid type, would be mentally precocious and physically frail. He would have a vertical stomach; the small bowel would be subject during early childhood to alimentary diseases. Certain ones of this type would have an acute costal angle; a long narrow chest; and a very active nervous system. On the contrary, a low thyroid type, or meso-ontomorph, would be physically well developed; have a transverse stomach; the small bowel would be very long and the large bowel very short. He would have a good digestion and metabolism. Between the two we have the hypo-ontomorph. The following history prepared by Professor Stockard is helpful in the classification of patients:

PERSONAL HISTORY.

Name..... Age..... Sex.....
Date of Birth.....Place of Birth (in mts. or not).....
F., Nationality.....Place of Birth.....

The importance of this classification has a direct bearing on some of the surgical problems with which we are confronted.

The procedure so largely in vogue during the last ten years, of fixing organs in certain positions to make them conform to a conceived anatomical standard, is in our opinion, a mistake in the light of our present knowledge of the great variation in size and position in different types. It is obvious that it would be incorrect to try to place the organs of a hyper-ontomorph in the position occupied by those of a meso-ontomorph. Now this is exactly what some surgeons have been trying to do by plication and other mechanical methods.

It is apparent that if a patient has a long narrow chest and an acute costal angle the most suitable position for his stomach is vertical, and any surgical alteration will be unfortunate. It is, therefore, fundamentally incorrect to try to convert this congenital type into something altogether different. This applies, with equal force, to the position of the colon. Plication, here, would be just as ineffectual as in the matter of the stomach. In fact, fixation of organs that should be movable is a surgical error. On the other hand, the fixation of movable organs that belong fixed, is surgically correct.

The cecum and sigmoid are two of the most variable organs in the body, and, when over developed, are responsible for many digestive disturbances often referable to the stomach. A large movable cecum, using the appendix as a suspensory ligament, causes reflex stomach symptoms that might be mistaken for ulcer or chronic appendicitis. So, also with a long sigmoid. In the former case, the appendix may have to be removed, even though it is not diseased, and if an elbow deformity of the ascending colon accompanies a large non-fused cecum, with a mobility of 180 degrees, it may require a developmental reconstruction for its correction.

Another problem of importance in these operations, and particularly in removal of the colon, is the question of the action of the ileocecal valve and the behaviour of an intestinal stoma. Not all animals possess the ileocecal sphincter.

I am firmly convinced, in the absence of proof, that the various segments of the alimentary canal are capable of initiating peristalsis; and this is borne out by the perfect functioning of a new stoma after the removal of part of the colon. I am further convinced, if the necessity arose, as it might in the case of multiple adenomata of the colon, with beginning malignancy, that the colon could be removed and function restored by attaching the ileum to the anus.

It is my firm opinion that in cases of movable cecum and anchored appendix a low grade infection starts in the appendix, and gradually ascends to the cecum and ascending colon, resulting in chronic appendicitis, perityphlitis, and colitis.

I have recently removed a colon of this kind, and the report of the pathological examination, by Professor Ewing is as follows: "Severe old chronic catarrhal enteritis and colitis. Hernias of cecal mucosa and wall. Marked chronic productive perityphlitis with adhesions and partial constrictions. Section shows chronic catarrhal colitis with extensive pigmentation of stroma cells."

Nonspecific and specific purulent infections of the colon, continuous, discontinuous, and segmental, are becoming increasingly common, and I feel that a great many of them originate in the cecoappendix. I believe the colon bacillus is frequently the offending organism. We have had five cases in all where the colon bacillus was the only organism found. Three of these were relieved by vaccines alone; two required operation because of complicating strictures. It is interesting to note in connection with these cases that all complained of indigestion and all were quickly relieved by vaccines or operation.

The remarkable gain in weight, particularly after a stoma, brings up the interesting question of the influence of any irritation—whether infection or tumor—on digestion. The wide distribution of sympathetic impulse in contradistinction to the localized influence of the central nervous system, together with the loss of tone engendered by local irritation, may offer some explanation of the symptoms accompanying this disorder.

One of the fundamental surgical principles involved in the treatment of infections of the colon is that when an infection has passed beyond medical treatment it can be cured by placing the stoma cephalad to the infection. There is a widespread misconception as to the inconveniences caused by a stoma, and the number of operations that have been devised to overcome these so-called inconveniences shows that there is some misconception, or lack of understanding, of the principles involved. The simplest method is always the best. And in my experience the bringing out of a loop and suturing it in position is entirely sufficient, regardless of whether the stoma is a temporary or permanent expedient.

In not one of the cases in which we have performed this operation has the patient complained of any inconvenience, and very seldom if ever, do they use any mechanical appliance other than a piece of gauze to protect against accidents.

The sympathetic nerve supply to the bowel is more or less segmental, and it may be that each segment of the bowel has a potential sphincteric control; so that when a segment becomes terminal

by operative procedure, a functional change gradually occurs and there is a slowing of the current as it approaches the end. Certain it is that some change takes place which permits the individual with a stoma to reassume control. In cancer, a stoma is of value only when used at the earliest possible moment after the tumor is discovered to be inoperable, and it is not of value when the patient is moribund.

Too often the surgeon delays till the bowel is obstructed and then such procedure merely hastens the end. The operation per se is one of the simplest in surgery, and except in fat people, can be performed under novocaine anesthesia.

One would think, from the multiplicity of methods that have been suggested and carried out, that an artificial anus functioned most unsatisfactorily; when, in reality, it functions perfectly. I frequently find that after an artificial anus has been made, a tumor, previously supposed to be inoperable, may be successfully removed on account of its diminution in size and the great improvement in the condition of the patient.

The small bowel is usually described as separated from the large by a valve—the ileocecal valve. Elliott has proved that this is not a valve but a sphincter muscle which contracts upon stimulation of the superior splanchnic nerves; and that its excitor cells are situated in the superior mesenteric ganglion. Langley and Anderson have demonstrated that the internal anal sphincter contracts on stimulation of the inferior splanchnic, and its motor nerves are situated in the inferior mesenteric ganglion.

The question then arises, what can surgery do to restore function in ileocecal insufficiency? The operation so far devised is conceived under a false impression of the anatomical mechanism and physiological function of this barrier between the small and large bowel. If the insufficiency is due, as it is in most cases, to a lack of sympathetic control, or perhaps suprarenal insufficiency, then no mechanical device known to surgery can avail. It is therefore conceivable that adhesions or an inflamed appendix, situated close to the ileocecal sphincter, interfering with its proper contraction would cause a loss of tone. Under these circumstances surgical interference for the removal of the appendix or of adhesions would allow the muscle to functionate properly and return to a normal state.

This is the only condition where surgery in ileocecal insufficiency can be considered justifiable.

ST. BARTHOLOMEW'S HOSPITAL.

ENCEPHALITIS LETHARGICA.*

BY W A. CAMPBELL, M.D.,

COLORADO SPRINGS, COL.

DURING the latter part of 1916 and the earlier part of 1917 there appeared in Vienna a pandemic which was first reported by von Economo and called by him "Encephalitis Lethargica." A like epidemic in Australia in 1917 was reported by Breinl as the "Mysterious Disease." In the earlier months of 1918 France and England were invaded. Its appearance in the United States was noted in the latter months of 1918. The paucity of the literature on the etiology, sympomatology, pathology, diagnosis, prognosis and treatment of this "Mysterious Disease" was a source of great annoyance and chagrin to the writer early in 1919. Even unto the present day there is little to be found in our literature on this subject tending to enlighten the internist in the treatment and outcome of these cases. With less than two hundred cases of the disease reported in the United States, in our medical literature, we are led to believe the disease in not as common as the reports in the lay press would indicate. Considering it a duty one member of the profession owes to all other members, when new questions arise, we place before you the history of an authentic case of "encephalitis lethargica."

*Read at the twenty-first annual meeting of the American Therapeutic Society, May 7 and 8, 1920.

Mrs. M. A. C., aet. 58, came to Colorado in 1890 with persistent cough. Examinations of sputum were then infrequent so we cannot say bacilli were found. Family history not good, mother, brother, and sister have died of pulmonary tuberculosis. Father living and hale at 92. Health improved and was pronounced well of cough after one year. Has enjoyed good health for 28 years with the exception of tonsillitis. Had tonsils removed twelve years ago. Gave birth to a healthy child twenty-two years ago. Menses ceased at 54 years. Felt exceptionally strong during 1918, weighed 152 lbs., blood pressure 145 mm. Hg. Took much interest in war work and knitting for the Red Cross. Started to Florida on pleasure trip January 10, 1919. Spent time while there in central and western portion of the State. Weather damp and cold while in Florida. Returned home on February 9. Travel home was on crowded trains with many returning soldiers. Contracted an infection of upper air passages on way home. This infection was not accompanied with fever, chills, or aching characteristic of influenza.

Exercised but little for several days after return home as she always felt the effects of altitude after being at sea level for a time. On February 14, went out during the afternoon to a social club. On the morning of February 15 she had double vision which persisted for forty-eight hours. Had no headache or nausea, but felt depressed. Sat with eyes closed to avoid seeing double. With the return of normal vision on February 17 a somnolent condition came on. Talking to or reading to her would not keep her awake. She slept well at night; would arise and dress herself in the morning, eat, and be asleep in a few minutes. She kept her eyes closed but it could not properly be called a pathological ptosis for she could voluntarily open them normally when she desired. This condition continued for ten days. She was put to bed with a nurse in attendance.

Realizing that we had a case of the "mysterious disease" to deal with we called in consultation internist, Dr. W. H. Swan, alienist, Dr. F. T. Stevens, oculist, Dr. J. R. Robinson, and bacteriologist, Dr. M. E. Staines. During the sleeping period, when aroused, she complained of severe pain in the lumbosacral region, inside of left thigh, and calf of the leg. The right leg did not hurt her. Her tongue became heavily coated and appetite obtunded. Her temperature varied from normal to 103°. Respirations normal. Pulse 90 to 100. By the end of the sleeping period there was a well defined paralysis of the right side of the face. Dreams disturbed her and held over from one sleeping interval to another.

Physical examination revealed the following conditions in the beginning of the second week: No tenderness of scalp; inability to wrinkle right forehead; vision normal; no disturbance in movements of eyes or changes in the fundus; pupils slightly larger than normal and they react to light and accommodation but do so rather tardily; profuse lacrymation with overflow of tears on right side. Sensation normal on right side of face; muscles inactive; cannot pucker lips; no abnormal condition on left side of face. Right side of face responds but slightly to faradic current but decidedly to broken galvanic current. Hearing normal;

tongue protruded without deviation; taste destroyed in right front quadrant of tongue; pharynx normal; swallows without difficulty. Heart sounds normal. Abdominal reflexes and others throughout body and limbs normal. Small dull area in lower portion of upper lobe of right lung; moist crepitant râles in base of both lungs on deep inspiration. Urine negative; 54 oz. in twenty-four hours, sp. gr. 1014, solids 52.16 gms., no albumin, no sugar. Blood: hemoglobin 94 per cent., red corpuscles 5,500,000, leucocytes 10,000, polymorph 66 per cent. No spinal puncture. Has one devitalized tooth, first upper left molar; recent *x*-ray showed no pus at root; gums in good condition. Muscular tremor in extended hands.

At the end of the third week all the foregoing symptoms were intensified. Mastication and the retaining of food and fluids in the mouth were more difficult owing to the biting of the inside of the right cheek and inability to control the lips in closing the mouth. Instead of ptosis the right eye could not be closed and to protect the cornea it had to be closed and bandaged most of the time. Lacrymation and tear overflow were increased. The whole face took on the mask-like expression, the eyes were sunken, and the skin smooth and waxy in appearance. The temperature ran lower, 99° to 100° in the afternoon. Blood pressure fell to 100 mm. and the pulse became very weak.

Pain continued in back, left thigh, and leg and was the only discomfort complained of. Speech was slow and voice changed. Mental condition very similar to that of typhoid fever in the third week. Delirium when half conscious. Urine voided voluntarily and frequently. Patellar reflex on left side increased. This was the most alarming stage of her illness. She continued in about the same condition until the fifth week of her illness.

Almost imperceptibly she began to show increased vitality in the fifth week. Intervals of normal mentality became longer; anorexia less marked; sleep more natural. Tachycardia was maintained. Complained of general muscular tension and could not get relaxed. Blood pressure increased and a steadier pressure maintained. Mental depression, in the form of the thought of impending dissolution and fear of injury to the family, was quite marked.

Feeling that recuperation would be hastened at a lower altitude (Colorado Springs being 6,000 ft. elevation) it was determined to take her lower. On April 10 she started for Excelsior Springs, Mo. She arrived there in fairly good condition. The hotel life seemed to excite her and a few days later she was taken to St. Luke's Hospital, Kansas City, and placed under the professional care of Dr. William F. Kuhn. While in the hospital tachycardia continued; temperature normal to 99.5°; tongue coated; leucocytes 10,000 to 11,000; polymorph. 68 per cent. to 74 per cent; hemoglobin 90 to 95 per cent.; urine negative; weight 126 lb.; mental disturbances about the same.

After two weeks she was taken to her old home in Ohio. Being slow in improving and recognizing the superiority of institutional treatment over home care, she was taken to Oxford Retreat, Oxford, Ohio, and placed under the care of Dr. R. Harvey Cook. Here she gradually improved, and her mental illusions and hallucinations disappeared. The leucocyte count remaining high, the conclusion was reached that the dead tooth ought to be extracted and, as there were but four teeth remaining in the upper maxilla, it was thought best to remove them all. This was done under local anesthesia. The devitalized tooth had quite a little necrosis at its apex. The cavity was thoroughly curetted.

She returned to Colorado on June 15. At that time she still had extreme weakness in the lumbosacral region and down the left leg accompanied with more or less pain. She walked with the attitude of one with stiff trunk muscles. Her tongue now cleaned off for the first time during her sickness. Her condition has gradually improved during the past eight months. The chief inconvenience now is the sense of exhaustion on moderate exertion. The paralysis of the right side of the face has gradually improved but is still in evidence. It gives no inconvenience except in the thought of its presence. The various organs of the body function normally. She now takes an interest in domestic affairs and plans for the future. Her brain functions normally and she is interested in reading. Her memory for past events is good except for the happenings during the first three months of her illness. This period is as a dream to her. Present blood pressure 128-70 mm., leucocytes 6,000, hemoglobin 90 per cent., polymorph. 75 per cent.

Recapitulation.—History: Family tuberculous; patient came to Colorado thirty years ago for health; good health for years past.

Condition at time of attack: Had been in Florida for a month; season cold and damp; crowded, unsanitary conditions on train returning from Florida; train congested with soldiers from southern camps; acute infection of nose and nasopharynx on arrival home; devitalized tooth.

Initial symptoms: Sixth day after arrival home arose in morning with diplopia which ended in forty-eight hours; no chill or sharp rise in temperature; no cephalalgia; no suboccipital pain; no general aching. Ate as usual and kept eyes closed on account of diplopia.

Later symptoms: Temperature rose gradually and reached 103° on fifteenth day and then gradually declined to 97° to 100° where it remained for ten weeks. Tachycardia persisted throughout the course of the disease and well along through convalescence. The assumed ptosis of diplopic period became pathological after the first three days and continued so for ten days. This was followed by opthalmoplegia in orbicularis and tensor tarsi muscles causing the right eye to remain open with profuse tearing and inability to wink the eye. No photophobia; no anesocoria; pupils slightly larger than normal, reacting sluggishly to light and accommodation; fundus normal throughout the whole course of the disease. Somnolence not profound; respiration regular and normal; no dyspnea; no dysphagia at any time. Mastication slow and difficult owing to inability to hold food and liquids in mouth due to paralysis of masseter and orbicularis oris muscles. Loss of sense of taste in portion of tongue supplied by fifth nerve. Parkinson's or leontiasis facies well marked and continued for several weeks. Disoriented for some time. Rosenbach's sign not present; Babinski's normal; Kernig's absent. Pain in lumbosacral region, adductors in left thigh and left calf constituted the chief inconvenience to patient and was most persistent. Tremor of limbs and feeling of rigidity in muscles continued well along in convalescence. Mental hebetude or psychomotor retardation was very marked during the height of the disease. Anxiety neuroses were marked, the patient required constant reassurance that she would recover. The psychoses manifested were delirium, hallucinations, and mild demonstrations such as we meet in athenic diseases. There were no periods of excitation or exhilaration. The blood examinations never showed impoverishment of the erythrocytes or hemoglobin. Numerous leucocyte counts showed from 10,000 to 11,000; this noted increase may have been partly due to necrosis about the root of tooth. Polymorphonuclear counts 68 to 74 per cent. Blood pressure normally 145 mm. fell to 100 mm. and went back to 128 mm. and is now 128-70 mm. Urine negative during whole course of the disease. Sputum showed streptococcus and pneumococcus.

Treatment: In general terms the treatment was symptomatic. During the first ten days rest in bed, salol, nutritious, non-stimulating diet, and an occasional laxative. When somnolence passed off and the patient became more or less restless sodium bromide, strontium bromide, and asafetida were given. The latter remedy proved to be the most effective, regardless of the fact that it is said to be an inert remedy and its therapeutic effects nil. Hot applications in various forms were beneficial for relief of the lumbosacral and leg pains. When pains were very severe, codeine was resorted to and during the course of the disease morphine was given three or four times. When asthenia became pronounced and blood pressure fell strychnine was tried without perceptible benefit and adrenalin was given hypodermically with good results. Hexamethylenamine was given, but results were questionable. Spinal puncture as a diagnostic measure was not deemed necessary, as the diagnosis was easily made from the symptoms and its use as a therapeutic agent could be only temporary. As the patient was very appre-

hensive, making the puncture would, quite likely, do more harm than the temporary good therefrom would justify. Care, kidness, reassurance, and pleasant surroundings proved the most efficacious general treatment. During her convalescence she had taken the syrup hydriodic acid and an elixir of pepsin. How much the former has had to do with clearing up the detritus in the brain or lesions left there it is difficult to determine. The elixir of pepsin proved a pleasant vehicle and since it contains 15 per cent. of alcohol was a mild stimulant. Much of the time since returning to the high altitude she has taken twice daily a cactus compound pill on the supposition that she would do better to have a mild cardiac stimulant after so severe an illness. It might be said the extraction of the teeth was a therapeutic measure. It is well to remove or eliminate any source of suspected or known infection.

Conclusions.—To make deductions from the study of one case is absurd. Having this case under observation led us to read all the literature we could secure. Several points have impressed us; (1) The etiology of the disease remains undetermined. Most probably it is originally an infection in the nasal passages. The fact that it follows in the wake a pandemic of influenza, or follows an attack of influenza, leads us to believe the specific infection is very closely indentified with, or is the same as that of influenza. (2) There is no well-defined syndrome of symptoms. From the large number of people who suffer from extreme weakness and significant nervous conditions after an attack of influenza we are led to believe there are cases of encephalitis lethargica that are so modified as not to be recognizable. (3) Facial paresis in the distribution of the motor branches of the fifth nerve and the portio dura of the seventh is common. (4) The acme of the disease is in the third week and is characterized by asthenia, weakness of cardiac muscles, and in fatal cases coma and death. (5) There is no specific treatment. All literature delineates the multiple symptoms but no one speaks in certain terms on the treatment. In this chaotic condition the treatment has to be left to the judgment of the attending physician. (6) The mortality rate is very high and should stimulate physicians in the investigation and treatment of the disease. (7) Epidemics of the malady as si infrequent that the study of the disease is practically limited to one or two years in the one generation of physicians.

424 North Nevada Avenue.

AN ACCURATE AND SIMPLE METHOD OF TESTING THE COAGULATION TIME OF BLOOD.*

By GEORGE R. LOVE, B.S.,

CHICAGO.

In a recent article, King and Murray[1] called attention to the fact that none of the current methods of testing the coagulation time of blood can be relied upon. They devised a method whereby the average coagulation time of normal blood was determined to be ten and one-half minutes, but with a variation of from eight and one-half to fifteen minutes. Cohen[2] has summarized the literature on the coagulation time in diseases as reported by several observers who used various methods. It may be noted that in the majority of cases the results are conflicting. This is due in part to the indefinite end-points and to the finger-stab methods, whose results one cannot hope to duplicate in a series of experiments, and, as King and Murray have demonstrated, may be misleading.

A method has been devised and has been used by this Department for the past year by which the coagulation time can be determined within twenty seconds. The end-point is definite and is entirely independent of the judgment of the operator. The method here described employs capillary tubes and resembles in principle McGowan's[3] capillary tube method. We have used this method only in venipuncture work, having abandoned finger stabs as of little or no value.

Preparing the Capillary Tubes.—Cut five millimeter glass tubing (lumen diameter 3.5 mm) into five-inch lengths. Heat the middle two inches of these tubes over a fish-tail burner until the glass is soft enough to sag into the burner by its own weight. Remove from the flame and immediately draw out until the whole is thirty to thirty-four inches in length. Break the tubes in the middle so as to form two equal-sized capillary tubes. The lumen must be from 0.3 to 0.5 mm in diameter.

Procedure.—Paraffin some short test tubes. Leave the test tubes and the capillary tubes in the room where the test is to be made until they are at room temperature. The temperature of the room must be constant and must be known within one degree.

The blood is procured in the usual manner by applying a tourniquet above the elbow and puncturing the median basilic with a short 15 to 18 gauge needle from above downward. The first few drops of blood are discarded and then one to two cubic centimeters are collected in the paraffined test tube. The capillary tubes are filled by dipping the drawn out ends into the blood and sucking it up rapidly to the shoulders of the tubes. The time is recorded when the blood first enters the capillary tubes. Two or three tubes are filled and the time noted when the blood enters each tube. The tubes are now laid flat upon the stand alongside a thermometer. At two minutes before coagulation should occur normally (*vide infra*), about two centimeters of the first tube are broken off and the separated part is held before transmitted light and broken between the fingers in such manner that the proximate ends may be drawn apart parallel to each other without injuring the thread of fibrin. This process is repeated at intervals according to the accuracy desired until the end-point is reached. The end-point comes when a thread of fibrin will stretch seven to ten millimeters across the break. The second and third tubes are not used if the end-point is reached in the first tube, except as a general check on the final end-point.

The time that the blood remains in the paraffined test tube before drawing it up into the capillaries must not exceed two minutes. Repeated experiments have been made which show that if the blood flows from the needle into the test tube in a stream, there will be no changes in the blood for two minutes which will affect the coagulation in the capillary tubes.

Addis[4] was the first experimenter who recognized the effect of temperature upon the coagulation time

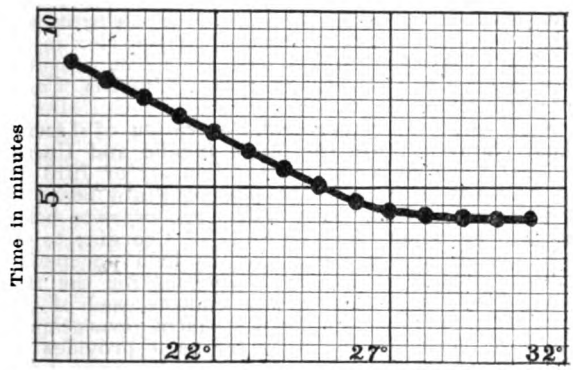
*Contribution from the Department of Chemistry of the Hahnemann Medical College of Chicago.

in capillary tubes. The temperature must be recorded or the whole test is valueless. The following chart gives the average coagulation time computed from a series of tests on twenty-six healthy dogs at different room temperatures. No appreciable variations were observed in the time of the coagulation of the blood from the different dogs.

TEMPERATURE COEFFICIENT

Temperature Centigrade	Normal Coagulation Time
18°	8′ 40″
19°	8′ 00″
20°	7′ 30″
21°	7′ 00″
22°	6′ 30″
23°	5′ 55″
24°	5′ 30″
25°	5′ 00″
26°	4′ 40″
27°	4′ 20″
28°	4′ 12″
29°	4′ 10″
30°	4′ 08″
31°	4′ 08″

After the temperature is recorded the chart is referred to and the coagulation time is translated into terms of 25° Centigrade.



Graphic representation of the Temperature Cofficient

In the illustration the foregoing data have been plotted, the regularity of the curve indicating the accuracy of the method employed. The curve seems to change its form at 29°, as though some new factor entered here. The general form shows that the coagulation of blood follows the law for ordinary chemicals reactions, an increase of 10° doubling the rate of the reaction.

In a series of experiments the author has had physicians, medical students, and nurses duplicate his tests, all the operators drawing from the same blood but working independently and with separate stop watches. The widest variation of all these duplicates was thirty seconds. These variations occurred only on the first attempts, the author's test always requiring the least time. This fact shows that the only skill necessary is in the process of breaking the tubes in such manner that the proximate ends may be drawn apart without injuring the thread of fibrin. Accurate results can be expected only when these instructions are followed exactly. The author has made repeated tests on the same animals at a constant room temperature and has calculated the normal coagulation time for each animal. In all these tests the greatest variation was less than fifteen seconds from the normal of that animal.

The advantages of this method over such a method as that described by King and Murray are obvious. The end-point is sharper and any poor technique in testing for the end-point before it is reached will in no way affect the final end-point. The marked effect of temperature is given by a chart and graphic representation. The method gives consistent results with inexperienced operators.

SPONTANEOUS CLOSURE OF LARGE VESICO-UTERINE FISTULA.*

BY GEORGE L. BRODHEAD, M.D.,

NEW YORK.

THE patient, 37 years of age, a sextipara, was admitted to Harlem Hospital on March 20, 1920. The woman said she had always enjoyed good health, and had previously given birth to five children without instrumentation. The puerperium had always been normal, and she has had no vaginal or abdominal operation. The last pregnancy began about June 25, 1919, and was uneventful up to the last two months, when the patient commenced to feel weak and had a profuse yellow vaginal discharge, with no odor or pain.

Labor began at 3 A.M., March 14, 1920, the membranes having ruptured at 11 A.M., two days previously, and her baby was born at 9 A.M., normally, after a six-hour labor. About ten minutes before the birth the woman was given a hypodermic injection, probably of pituitrin, and the patient states that she never had had such a severe pain as her last pain in the second stage.

For three days following the birth the woman stated she was well, and passed urine in the usual way. On the fourth day she "felt like a balloon," as if she was "going up"; probably caused by full bladder, or distended intestine, and she also complained of a hard swelling in the lower right abdomen, not painful to the touch. From this time on she had fever and chills, until she was admitted to the hospital on March 20, 1920.

For two days before admission she stated that she had passed urine in small amounts, but on the day of admission she had passed none, so far as she could judge. Upon admission the woman was found to be mildly septic, and she had a moderate, irregular rise of temperature and pulse for about four weeks, when she became normal. When the first examination was made at the time of admission a few clots were expressed from the vagina, and the cervix was found to admit two fingers, with more blood clots felt in the cervix. During the next twelve hours the patient was incontinent, and when she was taken to the operating room a blood-stained fluid escaped from the cervix. Further examination revealed a large opening, easily admitting the finger, leading from the region of the internal os into the bladder, from which urine freely escaped. The fistula was open for about three days, then closed and remained closed.

On April 19, 1920, Dr. Cherry of the Harlem Hos-

*Presented at a meeting of the Section on Obstetrics and Gynecology of the New York Academy of Medicine, May 18, 1920 (see p. 455).

pital visiting staff made a cystoscopic examination of the patient and gave me the following report:

The bladder capacity is normal, with normal bladder mucosa, and the ureteral openings are normal. On the posterior surface in the median line there is a contracted, retracted scarred area 1.5 cm. in diameter, surrounded by a slight area of congested mucous membrane. The fistula had closed. A solution of methylene blue injected into the bladder did not appear on sterile gauze, which had been placed in the cervix.

Vesico-uterine fistula is rare in itself, even following operative delivery, but occurring after a normal labor is practically unheard of.

The fistula may have been caused by a small rupture of the uterus following pituitrin, but, according to the statement of the patient, she passed urine normally for three days following delivery.

The closure of such a large fistula was remarkably rapid, especially in the case of one who had had a mild sepsis.

50 WEST FORTY-EIGHTH STREET.

SUPERNUMERARY BREASTS IN THE AXILLÆ (ANATOMICAL NOTE).

BY GEORGE B. LAKE,

COLUMBUS BARRACKS, OHIO.

MAJOR MEDICAL CORPS, U. S. ARMY.

MRS. S. W., housewife, aged 23½ years, presented herself April 15, 1920, complaining of pain and swelling in the left axilla. She was then about five months pregnant and gave a history of having had a similar swelling during a former pregnancy. Examination revealed a soft elastic non-inflammatory mass the size of a small egg in the left axilla, with very little pain or tenderness. Expectant treatment was advised and the patient was requested to procure a statement from the physician who had attended her during the previous pregnancy.

On May 22 she made the second visit, with a letter from her physician stating that she had suffered from an acute axillary abscess, which was incised and treated along recognized lines.

Family History.—Mother and father and two sisters living and well. Four children in family dead; two were premature, one sister died of "paralysis" at eleven years, one brother killed in accident. Patient is youngest child.

Personal History.—Had the usual diseases of childhood; none since. Menstruated at 13 years. Menses normal and regular, every twenty-four days. No sign of swelling under arms at time of catamenia. She was married in 1916 and became pregnant in December of that year. A child was born at 7 months and lived but 4 hours. One month before confinement (in July, 1917,) she noticed a slight swelling under the right arm and another more pronounced under the left. She noticed what looked like milk exuding from both axillæ, and this continued until October, 1917, after which the discharge ceased and the swelling subsided. Two days before her confinement the mass under the left arm, being large and tender though not inflammatory, was incised by the attending physician, liberating a considerable quantity of what looked like milk.

History of Present Trouble—In November, 1919, the patient became pregnant for the second time. A swelling appeared under the left arm early in April, 1920, and under the right about the middle of May. These masses are slightly tender, but the patient feels perfectly well in every way.

Physical Examination.—May 22, 1920. Normal breasts, large and well-formed from which colostrum is easily expressed. In both axillæ are soft irregular, elastic masses the size of a flattened egg, which have the consistency and feel of mammary tissue. There is no inflammatory reaction, and very slight tenderness. Pressure upon these masses produces a flow of fluid from openings high up on the anterior axillary folds on both sides. This fluid is microscopically identical with the colostrum expressed from the normal breasts. The accessory nipple on the right side is 3 millimeters in diameter, slightly prominent, and shows distinct nipple tissue; that on the left is smaller—scarcely more than a dimple or fissure in the skin.

In all other respects the patient appears to be a normally developed and robust woman.

Medicolegal Notes.

False Statements to Medical Examiner as to Medical Attendance.—Where an applicant for life insurance covenants in his application that the statements made to the medical examiner are true, and these statements are made a part of the contract of insurance and form the basis of the contract, the Georgia Court of Appeals holds that any variation in any of them which is material, whereby the nature or extent or character of the risk is changed, will void the policy, whether the statements are made in good faith or fraudulently. Generally, the question of whether any such variation is material or whether the nature or extent or character of the risk is changed is a question of fact to be determined by the jury. Irrespective of whether an osteopath who attended and treated the insured about a year prior to his death was a physician under the statute law of Georgia, the materiality and truth of the negative answers of the insured to the questions in his application: (1) "Have you consulted a physician within the past five years?" and (2) "Have you now or have you ever had epilepsy?" were, under the facts of the case, held to be questions for the determination of the jury, since the evidence was in sharp conflict both as to whether the insured in fact had ever had epilepsy and as to whether he knew the osteopath treated him for epilepsy rather than some slight temporary ailment which the law does not consider in determining what constitutes attendance by or consultation of a physician.—Southern States Life Ins. Co. v. Morris (Ga.), 102 S. E. 179.

A State Statute Authorizing Revocation of License Without Notice and Hearing Held Invalid and Unconstitutional.—Section 14 of the Georgia act of 1913 entitled "An act to abolish the present State board of medical examiners and to establish a composite board of medical examiners for the State of Georgia; to define its duties and powers," etc., is held unconstitutional and void in so far as it provides for the trial and conviction of a licensed physician accused of certain specified offenses, and the consequent revocation of his license. The section, in so far as it provides for such trial and the penalty upon conviction, is violative of the due process clauses of the Federal and State Constitutions, in that no provision is made in that section or elsewhere in the act for due notice to and hearing of the accused. A licensed physician was tried and convicted under the section, and appealed to a jury in the Superior Court, where he was again convicted, and then sued out a writ of error to the Georgia Court of Appeals, where the conviction was sustained. It is held that he could subsequently attack the judgments of conviction in the Superior Court and before the board of medical examiners, and, upon proper petition to a court of equity, prevent the enforcement of the penalties imposed by the act upon conviction.—State Board of Medical Examiners v. Lewis, Georgia Supreme Court, 102 S. E. 24.

Hypothetical Question as to Insanity Produced by Narcotics.—In a homicide case, where the accused claimed he killed the deceased while temporarily insane from using narcotics and intoxicants, the accused testified that he took three quarter grain morphine tablets, one about 6 A.M., one about 11 A.M., and one about 3.30 or 4 P.M. A witness saw him take two. His wife said she saw him take the one early in the morning. A medical witness testified that the taking of three quarter grain morphine tablets, each accompanied by a drink of whisky, would not cause temporary insanity, and that if the tablets were taken at intervals of three or four hours their effect could only be to make the accused sleepy. It was held that the hypothetical case was sustained by the evidence.—Cundiff v. State, Texas Crim. App., 218 S. W. 771.

ACTION OF IRON IN CHLOROSIS.

DESPITE the efficacy of iron preparations in chlorosis and other anemias we know as yet little or nothing of the modus operandi and Professor Nägeli of Zurich seeks to throw some light on the subject in *the Schweizerische medizinische Wochenschrift* for July 29, i, 31. It was Niemeyer who introduced the iron treatment of chlorosis into practice and he regarded the problem merely as one of adding iron to the hemoglobin molecule. But gradually it was shown that simplicity of explanation is not coterminous with truth and von Noorden sought to show that iron acts in these cases by stimulation of blood-making. This view in turn was antagonized by Meyer, and also by Morawitz and the arguments in favor of their position were numerous. It is easy to render animals anemic and then to study the action of iron on them, although chlorosis cannot be produced artificially. Incidentally it was discovered that rats can be completely freed from iron without the production of anemia. This fact harmonizes with another, that chlorosis is not necessarily attended with lack of iron. It is also realized that chlorosis is better considered as *sui generis* and not as form of anemia.

The author has studied a great number of chlorotic and anemic subjects while under iron medication, and finds that even by the second or third day there may be a pronounced reaction in the bone-marrow, as shown by the dominant number of young erythrocytes in the blood. In the case of a girl of 21 who for the past six years had developed marked chlorosis in the spring and fall, the myelic reaction in the blood was especially marked and in 3½ weeks all the chlorotic symptoms had vanished. The bone-marrow had shown a "stormy" activity and this initial activity subsided with the return of the subject to normal conditions. The leucocytes showed the same behavior as the erythrocytes. The phenomenon is akin to that seen when a blood toxic substance is administered and when bone metastases of malignant tumors occur. Evidently the old erythrocytes cannot be fed more iron and the cure comes about by engendering new blood cells with normal facility for taking up iron. The principle of curing anemias by iron is the same. There are old chlorotic subjects, however, who do not in the least respond to iron in small dose, nor to any form of organotherapy. But if these subjects receive very large doses of iron the results are brilliant, as is also the case in some secondary anemias; thus in the intense anemia of ulcer of the stomach the hemoglobin may be brought up to 100 per cent, transforming the appearance of the patient. Iron is then a specific stimulant of bone-marrow.

This line of research is continued in a second paper by Adler, an association of Nägeli, who deals especially with the matter of dosage. A number of favorite preparations of iron were tested in large dosage, comprising reduced iron, Blaud's pills, and compound tincture of iron. The dosage was such that half a gram of metallic iron was ingested every 24 hours under hemoglobin control. Naturally one begins with a much smaller dose and the large one is to be given only as indicated. A case is cited in which after Blaud's pills failed, ferrum redactum succeeded brilliantly; such experiences are not uncommon, so that not only large dosage but different preparations of iron should be tested. The case reports show many aspects of treatment. Several of the patients took an organic arsenical along with the iron. In most cases Blaud's or reduced iron pills were begun in small doses and the dose increased steadily until it was found that with a fixed dose the hemoglobin continued its increase to the desired point.

ATHLETICS AND INCREASING HEART DISEASE.

THE newspapers have given much space to the International, so-called "Olympic" games, at Antwerp during the past month, and each morning provided a first page story describing the various events in detail. This is significant as indicating the widespread interest of all Americans in athletics. We are, indeed, a sport-loving nation not only, but a sport-participating one as well. We love events which take place in the open. The huge crowds, the horse play, the unbounded enthusiasm of the spectators at the games, college or professional, appeal to us. We love the excitement and the noise. It must surprise the foreigners who visit our shores to be summarily carried to some stadium to see their first game of baseball. The meaning of it all is very bewildering at first, but soon they catch on to the rules of the game and begin to share its joys. Our soldiers introduced the national game in France and we are told that it has found a ready place in the list of events played out-of-doors in that country. England, too, has been partly converted to baseball and seems to like the innovation.

But to revert to the contests in Belgium, one finds a certain charm, almost a classic animadversion in the revival of the athletics of ancient Greece and Rome. Such words as discus, decathlon, pentathlon, and marathon take us back to the first-form period of our school days and revive memories, pleasant or otherwise, according to our scholastic talents or industry in pursuing roots and rules of

syntax. So much for the human interest side of the matter. But there is another side which appeals to the medical man, especially so if he happens to be interested in gymnastics or physical exercises carried out with the purpose of improving the health, or laying the foundation in boyhood of a sound body in which a sound mind can possess a fitting temple throughout the span of coming years. It is one thing to carry out strenuous exercises for the sake of one's own increase of physical endurance; it is quite another thing to enter into a competition where every nerve and sinew is strained to the breaking point for the sake of defeating a rival from another country. The contest of 1920 seems to have been productive of overexertion to the point of actual injury. In one of the newspaper reports we read the following: "Rudd collapsed just as he crossed the finish line. Campbell caved in fifty yards from home. He was out fully five minutes. He was attended by a physician, who had to resort to artificial respiration before he recovered sufficiently to leave the field."

Now, under such a strain all vital organs are severely taxed, but most of the work falls upon the heart, using up its reserve. The right heart cannot empty itself quickly enough, the lungs are filled with blood which cannot be properly oxygenated, the inhibitory action of the vagus is reduced to its lowest terms, and the heart runs wildly away. The heart muscle is strained permanently, and there result both dilatation and hypertrophy—the so-called athlete's heart.

Modern civilization is making great demands on the heart, greater than many physicians even can realize. In this city we have an Association for the Prevention and Relief of Heart Disease which has compiled some very surprising statistics. For instance, during the year 1916 there were in this city 10,682 deaths from organic heart disease alone, while the deaths from tuberculosis were 9,622, and from cancer 4,702. Investigation clearly indicates that much heart disease is distinctly preventable. Accidental infections by way of tonsils, adenoids, and teeth can be greatly reduced and thus the body can be spared the great struggle with bacteria and their toxins in so far as these foci are concerned. If this be true of infections which may cause cardiac disease, how much more is it true of violent and excessive exercise carried far beyond the line of reserve. There is a great deal of falsity about the assumed value of exercise in the open air. In moderation, that is within the individual limits prescribed by bodily limitations fixed by Nature for each person, nothing is better. Proper exercise is as essential as food or air, but the growing boy in his excess of enthusiasm and knowing no limits to his endurance greatly oversteps his bounds in many cases and invites disaster. It is a common sight at twilight on summer evenings to see boys and young men clad only in the lightest of togs running along the line of Central Park or even around it "if the wind holds good." These excursions are often looked upon as endurance tests, and are centered upon time and distance rather than upon speed. They make very urgent and prolonged demands upon the heart, and are beyond doubt very damaging to many. It is a mistake to assume that civilized man can perform and endure like the uncivilized. Centuries of inbreeding and adaptation to environment have changed the human machine into a stronger mental and a less strong physical mechanism. In other words, the bodies of most men are better adapted to demands of a mental nature, such as quickness of decision, constructive planning, etc., rather than to tasks demanding mere brute strength. There are, of course, those among us who still possess the latter to a remarkable degree, but their number is probably diminishing. A little more insistence on this point by physical examiners and instructors might bring about much good to the youth of the land.

PNEUMONIA WITH DIARRHEA.

PNEUMONIA will undergo its evolution in most cases (90 per cent. according to Triboulet's statistics) without the occurrence of diarrhea, nevertheless diarrhea may arise at the time of defervescence as a critical phenomenon of the same nature as diuresis, but in these circumstances the intestinal disturbance cannot be regarded as an abnormal symptom. In some cases of pneumonia, the diarrhea, instead of occurring only at the time of the crisis, may be prolonged for several days and be quite rebellious to treatment. It is no longer a good sign announcing the advent of convalescence, but on the contrary becomes an almost certain symptom of pneumonoenteritis whose results are always to be feared. The diarrhea, although not serious in itself, nevertheless possesses considerable value from the viewpoint of prognosis. It appears to be closely related to the evolution the disease will follow and from this standpoint it has an interest of the highest order. In frank pneumonia, the lung alone should be involved, the intestinal mucosa remaining intact, so that every unusual phenomenon occurring in the bowel should lead the physician to fear a dissemination of the pneumococcus in the organism, as well as a special virulence of the bacterium in question. It has been noted by good clinical observers that when diarrhea occurs in pneumonia before the advent of defervescence some complication, such as otitis, purulent pleurisy, or suppurating arthritis, is prone to arise.

If the loose stools are examined they will be found to give a distinctly acid reaction to litmus paper. The sublimate-acetic acid reagent, as used by Triboulet, will give valuable data. In subjects with an intact intestinal mucosa, the liquid bathing the deposit in the lower part of the test-tube is cloudy and offers a pink hue. In the case of infectious pneumococcal diarrhea, the liquid is almost limpid or hardly cloudy, while the deposit, instead of being pink, is grayish and occasionally putty colored.

During measles, especially in hospital patients, it is not uncommon for secondary infections to arise—otitis, empyema, etc.—many of which are due

to the pneumococcus. This association of diarrhea and secondary infections due to the pneumococcus in measles has been clearly demonstrated by Triboulet by systematic studies of the stools. Rilliet and Barthez years ago stated that diarrhea is much more common in abnormal measles, and if to the pulmonary inflammatory processes an enterocolitis becomes added, the case will end fatally. It is not probable that the diarrhea in measles is the awakening of a former attack of enteritis and it would seem logical to admit that there exists a relationship between the diarrhea and the gravity of the pneumonia, and that the appearance of this complication denotes a peculiar gravity of the affection.

THE SURGICAL TREATMENT OF CHRONIC GASTRIC ULCER.

CHRONIC ulcers of the body of the stomach—and among them ulcers of the lesser curvature—should be individualized as much from the clinical and pathological viewpoints, as from the standpoint of the surgical therapeutics to be employed. A symptomatology peculiar to them will allow them to be diagnosed clinically, while a radiological examination admits of a certain number of diagnostic data belonging properly to them. Their evolution is very frequently rebellious to any kind of medical treatment which neither relieves the patient nor prevents the development of gastric deformity that these ulcers invariably bring about sooner or later. The most frequent of these deformities is that which results from a midgastric stenosis of a progressive tendency ending in gastric biloculation. A bilocular stomach, the result of ulcer, does not constitute a complication dependent upon the cure of the extinct lesion. While in some cases the midgastric stenosis is of a purely cicatricial nature, there are hosts of others in which the lesion—ulcer—is still active. The symptomatology of this process depends quite as much on the ulcer itself as upon the midgastric stricture that results from it.

Chronic ulcer of the body of the stomach and gastric biloculation resulting from it are amenable to surgical treatment having in view the removal of the lesion. Palliative operations give only uncertain and rarely prolonged results in cases of gastric ulcer and gastric biloculation. Annular excision of the midgastric segment—the seat of the ulcer or that of the stenosis resulting from it—should be the treatment of choice for these lesions, even when they are adherent to the surrounding viscera, but only when they are not too extensive transversely. Very extensive ulcerative lesions, with or without biloculation, and those coexisting with a pyloric ulcer, should be dealt with by still more extensive resection, pylogastrectomy, followed by Billroth's second method of suture.

The general condition—frequently very precarious—of subjects with inveterate lesions is alone responsible for the still high mortality of these radical interferences. If an early operation is resorted to, that is to say as soon as a fair trial of medical treatment has shown it to be futile, the operative mortality will be reduced in notable proportions. Resort to gastroenteroanastomosis and jejunostomy will save patients who are in a cachectic state but later on, when an amelioration has taken place, excision of the lesions should be undertaken, since the improvement resulting from the palliative operation will merely be temporary.

MEDICAL TREATMENT OF ILEUS.

DOCTOR ESCOMEL of Arequipa, Peru, contributes the leading original article in *El Siglo Medico* for June 12, 1920, lxvii, 3470, dealing with the above subject. He reports five cases which ended successfully without operation. The first patient was an old lady with an irreducible umbilical hernia with eventual intestinal obstruction. Operation was out of the question by reason of organic heart disease. Beginning at 8 A. M. the patient was given a spoonful of liquid vaseline every half hour. At 2 P. M. the obstruction disappeared spontaneously, the hernia having reduced itself, and all of the symptoms subsided. In the second case the patient was also an elderly woman with right inguinal hernia. Strangulation developed suddenly at night, with symptoms of ileus. Liquid vaseline was given every quarter hour with the best of results. The third patient was likewise an elderly woman with a reducible umbilical hernia which developed symptoms of incarceration and ileus. The treatment and result were the same as in the preceding case. The fourth patient was an old man with malaria, who developed while under treatment symptoms of ileus. There was no hernia. The diagnosis was intra-abdominal invagination, and the treatment and result were as in the other cases. The fifth patient was a middle-aged woman with symptoms duplicating those of the fourth case, and the treatment and results were as already stated. The author has had sixteen such cases, all told, but it is not necessary to cite further examples. In some of them he gave injections of pituitrin. It is sometimes stated in literature that hot, strong coffee is used by Spanish people as an emergency remedy in irreducible hernia, but Escomel does not allude to it. In his summary he advises the use of liquid vaseline before proceeding to operate, and he would wait about five hours to give this resource a fair test. Naturally in hernias he would make use of a mild taxis and would inject pituitrin into the muscles on theoretical grounds.

WAS THE "LEPER" OF GRÜNEWALD A VICTIM OF ERGOTISM?

PROBABLY no work of art commemorating a physical disease has caused greater interest in the profession than a supposed leper painted by Matthias Grünewald about 1509. Thibièrge discusses it exhaustively in the *Annales de dermatologie et de syphiligraphie* for June, 1920, vi, i, 3. The subject of the picture is the "Temptation of Saint Anthony," the patient being one of numerous figures. By an odd coincidence Thibièrge reached the conclusion that the disease depicted was ergotism, a condition not at the time known to exist as a mass food poisoning, but which was most commonly known as Saint Anthony's fire. This opinion was

also published long ago by Huysmans, but the coincidence of the person of the saint and the malady known by his name is apparently not thought to have been a factor in including this figure in the scene. Keller and Virchow thought the disease was syphilis, while many, including Charcot and Meige, have regarded it as leprosy. Thibièrge sums up the lesions in the afflicted man as follows: Pustules over a considerable area, subcutaneous suppuration suggesting gummata, ascites, and mutilations of the extremities. From what is known of this painter's art he used a model to paint this figure, and the model doubtless presented many if not all of the lesions depicted. The suppurations and subcutaneous lesions, as well as the ascites, were doubtless secondary, and due to the cachectic state of the subject, but as for the nature of the mutilations the author, after comparing them with numerous illustrations of gangrenous ergotism in the magistral work of Ehlers, is forced to conclude that the case could not have been leprosy or syphilis and by consequence was probably ergotism.

The Throat in Botulism.

Vernieuwe of Ghent has had occasion to study a series of cases of botulism which he reports in the *Revue de laryngologie, d'otologie et de rhinologie* for June 15, 1920, xli, 11. As a result of study of this material he found paralysis of the velum palati associated with the visual disturbances reported by authors, and great muscular weakness and prostration. This triad of symptoms points strongly to botulism, but it becomes necessary to exclude postdiphtheritic paralysis. In one case cited the young woman spoke in the accents of velum paralysis and incidentally remarked that she "saw as through a fog," and could not read or sew. The author at once thought of postdiphtheritic paralysis, and put the question, getting the reply that one month before her infant had suffered from that malady. The author was now convinced, but learned the next day that the patient's brother also presented the same symptoms. The sister developed later a special dryness of the throat comparable to the action of atropine. The brother complained of extreme thirst and crises of dyspnea. The author does not inform us as to just when and why he changed his diagnosis, but it was learned that the two patients and six others had partaken together of raw ham. All eight patients developed, in consequence of the extreme dryness of the throat, necrotic ulcers. All eight had accommodation paralysis, but only four had velum paralysis. The cases were of mild type, and all ended in recovery. In discussing the nature of botulism the author cites authority to show that it is a form of ptomaine poisoning because the *Bacillus botulinus* forms a poison known as ptomaatropine. Most authorities make a distinction between botulism and ptomaine poisoning proper.

"Bankruptcy of German Science."

In an editorial in the *Journal de médecine de Bordeaux* published last winter attention was called to the fact that a recent German book on bacteriology had deliberately suppressed all reference to French and American authorities. The Medical Record, in its issue of May 15, expressed the opinion that the German in question may have been unable to secure access to recent works of the Entente nations. An Austrian was cited who under similar circumstances had apologized for failure to cite foreign authorities. We suggested that under the circumstances it might be just to give the Teuton the benefit of the doubt rather than to look upon the omission as new propaganda. Professor Cruchet, editor of the *Journal de médecine de Bordeaux* for June 10, 1920, xci, 11, courteously dissents from our stand and holds that the suppression of mention of our authorities was deliberate. He devotes his editorial page to the justification of his position with the above mentioned caption. He is certain, apparently, that a new propaganda is already in operation. There is a strong motive for one, because German science has nearly gone bankrupt as a result of five years of isolation, while conversely France has made notable gains in prestige. For fifty years Germany sought to force French science into the background, and there is no doubt that she will seek to renew her machinations in the years to come. Hence in any case of failure to mention the work of its old antagonists, the presumption, Cruchet thinks, is not unreasonable that such suppression has been calculated.

News of the Week.

Child Labor Safeguards.—In its preliminary report the permanent Committee on Standards of Physical Fitness for Children Entering Employment, appointed by the Children's Bureau of the United States Department of Labor, a minimum age of 16 years for entrance into industry is recommended, on the ground that the period immediately preceding this age is a time of special strain for the child. Complete physical examinaton before a child is pronounced physically fit for the particular occupation contemplated, reexamination when changing occupation, and further scientific study of the effect of different kinds of work on the physique of boys and girls in their teens, are some of the recommendations made.

Bubonic Plague in the Turkish Army.—According to press advices four cases of bubonic plague have been discovered in the Turkish government barracks at Scutari, across the Bosphorus from Constantinople. The Allied Sanitary Commission has forbidden the landing of boats at Scutari.

Strike of Spanish Physicians.—Physicians and surgeons of Saragossa, Spain, are reported as having refused to treat any cases of sickness among Communists.

Valhalla Neurological Hospital.—Arrangements have been made for the formal opening on October 1 of this institution for the exclusive study and treatment of diseases of the central nervous system, under the auspices of the King Solomon Hospital Association. The hospital is situated on the site of the old Quaker School in Valhalla, Westchester County, N. Y. It covers twenty-five acres of wooded hillside and eighteen buildings, a tennis court, croquet, and athletic grounds are ready for use. A drive for $500,000 is to be conducted for the maintenance of the institution.

General Hospital No. 1 Destroyed by Fire.—The sixty-one unoccupied frame buildings at Bain-

bridge Avenue and Gun Hill Road, the Bronx, which constituted General Hospital No. 1, also known as Columbia and Williamsbridge Hospital, were completely destroyed by fire last week. The buildings, which were abandoned as a hospital six months ago, had been sold to a contractor, who had commenced their removal. The loss was placed at $50,000.

United States Denounced by Russian Reds.—At a recent meeting held in Madison Square Garden, New York City, under the auspices of the Soviet Medical Relief Committee, this country was roundly denounced by some of its citizens as well as its undesirable alien guests for refusing to permit medical aid shipments to Russia. Secretary of State Colby subsequently took the trouble to cite instances, in rebuttal, of shipments of medicines and relief supplies sent by this country to Russia which were confiscated by the Soviet military authorities, consequently never reaching the civilian Russians for whom they were intended.

Eviction of Clinic Denied.—The newspaper story to the effect that the Children's Orthopedic Hospital Dispensary in Brooklyn had been ordered by the Brooklyn Association for Improvement of the Condition of the Poor, which owns the building, to vacate or buy the premises by September 10, is denied by the director of the association and the circumstances explained.

Memorial to Gorgas.—Señor Don J. E. Lefevre, chargé d'affaires of the Panama legation, Washington, D. C., announced on August 22 that the government of Panama would give $1,000,000 to St. Thomas's Hospital for the establishment in Panama of an international institute for the study of tropical diseases. The matter will be taken up with the Rockefeller Foundation.

Dr. George Chaffee, formerly of New York City, has opened his office at 100 Hawley Street, Binghamton, N. Y.

The High Cost of Complexion.—"According to the figures," the women of the United States pay a luxury tax of 10 per cent. on cosmetics to the amount of $750,000,000 a year.

Professor Wilhelm Max Wundt, German physiologist and philosopher, died at Leipsic August 31. He was born in 1832, studied medicine at Tubingen, Heidelberg and Berlin, and served as lecturer at Heidelberg and professor of philosophy at Zurich and Leipsic. In Leipsic he founded an institute for experimental psychology. He was a voluminous writer on philosophic subjects.

Obituary Notes.—Dr. GEORGE L. MILLER of Omaha, Neb., who gave up the practice of medicine many years ago to enter the journalistic field, died Aug. 28, at the age of eighty-nine.

Dr. FREDERICK CLARK BRADNER of Englewood, N. J., died suddenly Aug. 30, at the age of forty-six. He was graduated from the College of Physicians and Surgeons, New York City, in 1899, specializing in surgery. He was a member of the American Medical Association and of the State Society.

Lieut. JOHN H. WEAVER, U. S. M. C., who had been on duty at Quantico, Va., died in the Naval Hospital at Savannah, Ga., Aug. 27, from injuries received in an airplane crash. Lieut. Weaver, who was twenty-five years of age, entered the Air Service in 1917.

Correspondence.

ALL GERMAN, AUSTRIAN, AND TURKISH SURGEONS EXPELLED FROM THE INTERNATIONAL SURGICAL SOCIETY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—All right-minded American physicians and surgeons will heartily approve of the clear and decisive action taken by the International Surgical Society, which held its triennial Congress at Paris, July 19-22 of this year, under the presidency of the distinguished Dr. W. W. Keen of Philadelphia (its first meeting since April, 1914); the following is from the *Gazette des Hôpitaux* of July 31, 1920:

"The official languages of the Society shall be French, English, Italian, and Spanish (the latter taking the place of the German language, which has been dropped). The Society ratifies unanimously the expulsion of all German, Austrian, and Turkish members, and adopts, also unanimously, the following motion:

" 'The International Surgical Society, basing its work upon the application of methods of pure science, deplores the fact that men of supposed wisdom and information so stultified their consciences as to sign the German manifesto of Oct. 4, 1914, a statement full of erroneous and lying affirmations; that their reason was not able to preserve them from such an outrageous, dastardly action (*vilénie*); and that their hearts have not dictated the slightest retraction *after* the falsity of their statements and accusations has become evident and proven. This deplorable renunciation of methods of discussion and of scientific control leads the International Surgical Society to strike from the list of members of the Society the names of all members from the Central Powers and of all other surgeons who have united (*solidarisés*) themselves with them.' "

Clear, concise, to the point, and easily understood. A splendid action!

CHARLES A. POWERS, M. D.

DENVER, COL.

THE NATURE OF CANCER.

To the Editor of the MEDICAL RECORD:

SIR:—I hardly think there is any reader of my article, "The Cancer Enigma," which appeared in the MEDICAL RECORD of February 28, who will view the reference to this article by Dr. Edward Percy Robinson as a fair criticism. He lumps up in an unusual manner, without much reference to the context, certain statements I have made, and describes them as "gunshot" in character. Well, I can hardly agree to this definition, as my agent is not a gun, but rather a spray of printer's ink, resulting in an array of words by which it is my aim to give expression to a little common sense with which to gain entrance to the minds of my professional brethren. I do not employ a gun which is dependent upon an explosive compound, usually to a large extent made up of "nitrate of potash," for I have known of this salt being employed mixed up with molasses as an old wife's cure for cancer ever since I can remember, and without any apparent beneficial result, so far as I could ascertain.

No, cancer is a blood disease which has resulted

from persistent autotoxemia. Thus healthy cell metabolism has been gradually replaced by cell metamorphosis, which has resulted in these metamorphosed cells departing from physiological control, and assuming the character of fungi. These grow *upon* and not *within* the tissue, as benign tumours do. Moreover, these are able to exist and thrive only upon a vitiated soil, which in this instance is the blood. I may remark that fungi likewise are able to exist only upon a polluted soil.

Now, so long as the thyroid gland is in a healthy condition healthy cell metabolism will continue; but this can only be the outcome of this gland and every other gland being supplied by non-toxic blood. Otherwise its functional activity will be reduced, and so we invariably find that hypothyroidism is in existence. Moreover, there also coexists atrophy of this gland in cancer subjects.

Does Dr. Robinson believe that "the cause of cancer is an excess of salt"? Does he imagine for a moment, that the blood is such a futile colloid that it would tolerate, for an hour, an excess of salt, or the kidneys be accessory to the act? If so, I should have been a victim of cancer long ago. No, Sir, in the presence of cancer we must fortify the functional activity of the partially, or perhaps it would be more correct to say the seriously, disabled condition of the thyroid by supplementing its functional capacity by thyroid therapy. Dr. Robinson forgets to state that the patient he refers to was turned out of one of our largest hospitals, suffering from extensive cancer of the stomach, and given two months to live, and yet recovered under dietetic, hygienic, and thyroid treatment. And I could relate several similar happy results.

Dr. Robinson states that my article "is interspersed with remedial agents, and in no one instance gives a logical reason for their use in the treatment of cancer, nor what a cancer is, or on what theory he works to bring about his cures." In reply, I would aver that the days of "theory" with me have long since passed. I work upon a definite plan, which has for its foundation definite practical results. I have already in this communication stated —what I have, beyond doubt, proved—what "cancer is"; and I know that its incidence is due to two principal factors: First, a deficiency of vitols and organic salts in the form of colloids—not chemical salts—due to living so largely upon *devitalised* material, which has also had these organic vegetable salts removed from it by ignorance of the conservative method of cooking, where cooking is thought to be necessary. And second, to persistent constipation, resulting in a constant influx of decomposing and offensive toxic material into the blood stream, by which every cell of the body is bound to suffer in its functional duties, and therefore in its character. Hence it becomes cancerous.

ROBERT BELL, M.D.

15 HALF MOON STREET,
MAYFAIR W., LONDON.

ARTIFICIAL PNEUMOTHORAX.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I have been requested by Prof. U. Carpi, of Lugano, Switzerland, the general secretary of the International Association of "Pneumothorax Artificialis," to translate the following circular and to cause it to be published in as many of the American medical journals as will be willing to give it space. May I ask you to extend to it the hospitality of your esteemed paper.

S. ADOLPHUS KNOPF, M.D.

INTERNATIONAL ASSOCIATION OF "PNEUMOTHORAX ARTIFICIALIS."

The International Association of "Pneumothorax Artificialis," of which the work was paralyzed during the long war, desires to resume its activity by inviting all former members of the association to renew their subscription and all other physicians interested in artificial pneumothorax to send their names and addresses to Prof. Umberto Carpi, Lugano, Switzerland, and to become members. The purpose of the association is to spread all practical and scientific information concerning artificial pneumothorax. Although induced pneumothorax for therapeutic purposes has become remarkably prevalent, it has remained a therapeutic procedure applied only by physicians specially trained and experienced in this operation. For the convenience of the patients who may be obliged to change their residences, to know the names and addresses of physicians who practise artificial pneumothorax is of great value, in order that the patient may continue the treatment by periodic refilling. A complete list of physicians practising artificial pneumothorax will be published in *Pneumothorax Thérapeutique* for 1920-1921, edited by Carlo Forlanini. This list will be sent to all the members and to the most important medical societies, medical academies, and similar institutions of the different countries. In the journal will be enumerated and discussed all the world's literature on pneumothorax. The association will continue its labors under the policy indicated by the illustrious master and creator of artificial pneumothorax therapy. As soon as the finances of the society will permit the renewal of the publication, the editor will put himself in communication with the editors of such medical journals of other countries as are publishing articles on artificial pneumothorax. For the present these are "die Sonderhefte des Tuberkulose Centralblattes ueber Lungenkollapstherapie" and the collected monographs in the journal "La Tuberculosi," which appears in Rome. [I trust that our very excellent *American Review of Tuberculosis*, edited by Prof. Allen K. Krause, of Baltimore, will be included in this list. S. A. K.]

The subscription price of 5 francs should be sent to the general secretary, Prof. U. Carpi, Lugano. The subscriber is entitled to receive the journal with the list of names. Those who desire to receive the monographs of the journals indicated should make a request for them to the general secretary, who also has an international exchange office for all publications appertaining to artificial pneumothorax. Summaries in English, French, and German on any topic relating to artificial pneumothorax will be gratefully received and published.

DE SENECTUTE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Your editorial on this subject is pleasing and correct, so far as it goes, but there is one omission which I wish to supply. To my mind, the greatest happiness as one touches the end, is still, if possible, to be useful. And that is, or should be, the crowning glory of the good physician's life. So long as life lasts, if he preserves his mental grasp, he can still counsel, advise in a way that, if heeded, will bring health and happiness to many. In that is his great comfort and joy. And just there is the wide gap that separates the good old practitioner of former days—and alas! a very few at present—from even the renowned specialist of to-day.

B. R., M. D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 13, 1920.

The London Hospital's Need.—Lord Knutsford, chairman of the London Hospital, explained on August 7 last to a representative of the London *Times* the situation of the London Hospital at the present time. He said that its position was so critical that unless some superlative philanthropist would endow it to the extent of £2,000,000 or more the alternatives were Government aid or the closing of the hospital. He had already made written representations to the Chancellor of the Exchequer without success, but the matter was now at his further request, receiving the consideration of the Ministry of Health. They could not go on as they were. There was enough money to carry them over to the end of November of this year. The appeal made in the *Times* last May had resulted in subscriptions amounting to £40,000, the King's Fund had granted £35,000, and £12,000 had been received from the Hospital Sunday Fund. A "lucky legacy" recently also benefited the hospital to the extent of £10,000, which sum, however, would probably not be available within a year. The estate owned by the hospital was worth from £12,000 to £16,000 annually, but all securities were pledged to meet the debt to the bankers now amounting to £100,000. Last year patients in the wards and their friends between them contributed £10,000 to the funds. Now force of circumstances had compelled the fixing of a charge on all patients of twenty-one shillings a week toward their maintenance. But the hospital under modern conditions had to face an expenditure of a quarter of a million to £300,000 annually. The wages bill had increased from £40,000 to £80,000. There were 700 nurses and 200 more would have to be added when the bill providing for a nurses' forty-eight-hour week became law. It was not that the public was less generous. High prices alone were responsible for the present situation. With regard to state assistance, he said it was absolutely essential if the London Hospital, and, indeed, all the great hospitals were to remain open. What his committee wanted was to be enabled to run the hospital on its own lines as heretofore with a sufficiency of funds guaranteed by the Government. If it were said that the country could not afford to give this support, was it not better to pay in that way rather than in the myriad of evils to which the neglect of thousands of sick people would give rise?

National Health Insurance.—A memorandum dealing with some of the medical aspects of the British National Health Insurance Act drawn up by Sir Thomas Mackenzie and the staff of the St. Andrew's Institute for Clinical Research has been issued as an appendix to the report of the Inter-Departmental Committee appointed to consider and report upon the form of medical record to be prescribed under the terms of service of insurance practitioners contained in the Medical Benefit Regulations for 1920. In previous London Letters reference has been made to the methods for prevention of disease devised by Sir James Mackenzie, and it may be said that the memorandum has been compiled with the intention of indicating the principal defects in medical knowledge which exist at the present time and which impair the success of the act and also to point out certain means which can be taken to remedy them. The following is a summary of the memorandum: (1) The present phase of medical knowledge is defective, because the classification of disease is largely based upon pathological changes discovered after death, which bear little or no relation to the clinical manifestations of ill-health and no relation to the early symptoms of disease which occur before structural changes can be recognized; (2) advance in knowledge along the right lines can be effected only by making use of the opportunities of the panel doctor; (3) encouragement must be given to the panel doctor to make use of his opportunities for improving medical knowledge by: (a) encouraging him to keep brief records of his cases and of the symptoms presented on the lines indicated; (b) issuing to him from time to time notes upon the mechanism and the significance of symptoms; (4) by improvements in medical education in affording some instruction on clinical medicine as studied and treated in general practice as apart from its study under hospital conditions; (5) in view of notes of cases kept by a practitioner as indicated certificates of fitness or unfitness for work should be accepted apart from a definite diagnosis in the numerous cases in which a true diagnosis is not as yet attainable; (6) by the co-ordination of workers, clinical and laboratory, the progress of medicine can be favored, and the more skillful treatment of panel patients facilitated.

Discussion on Industrial Efficiency and Fatigue.—The Congress of the Royal Sanitary Institute was held in Birmingham July 19 to 24. In the Section of Industrial Hygiene, which took place on Tuesday, July 20, Professor E. L. Collis, a member of the Industrial Fatigue Board, read an admirably instructive paper on the subject. He pointed out that while the human body may be considered as a machine which requires fuel in the form of food to enable it to perform work, at the same time it is a living machine, the structure of which is in a constant state of metabolic activity, building itself up and breaking itself down; that the internal activity of building up—so-called rest—is a direct incentive to the external activity of breaking down or work; that work is even more necessary to health than rest; that fatigue, the result of sufficient work, is a healthy phenomenon, the forerunner of healthy rest; but that without sufficient rest over-fatigue results which manifests its presence as ill-being, physical and mental, a lowered capacity for work and for resisting sickness, associated with bad temper and discontent. Physical work which is performed by the muscles is directed by the brain; both muscular and mental activity steadily increase with practice which, if uncontrolled, would bring the organism to a state of excessive exhaustion. This state is guarded against by the mechanism which transmits messages to the muscles; here, in the synapse in the spinal cord through which the efferent impulses must pass, a block arises; the

coming into existence of this block, while both muscular and mental activity may be increasing through practice, constitutes the onset of fatigue. Over-fatigue lowers industrial efficiency and the standard of well-being; thus the objectives of maximum production and maintained health depend on its avoidance. The interests of national productivity and of national health are in this matter the same, the avoidance of over fatigue. When output is increasing hour by hour during the day, and day by day throughout the week, there can be no accumulation of fatigue; ill-health is then kept at arm's length. When output is falling off as the day lengthens, and as the week progresses, fatigue is accumulating, the *joie de vivre* is diminishing, and discontent is appearing.

Much could be done to improve efficiency and prevent over-fatigue. Labor turnover, an economic waste which in factory employment alone places upon industry a yearly burden of some 40 million pounds, due to the rolling stones of labor trying to find proper holes to fit into, is productive of much unnecessary inefficiency and over-fatigue. It can, according to Collis, easily be reduced 70 per cent. and probably more by medical and psychological selection of workers for work, instead of adhering to haphazard, come-and-go-as-you-please methods of engagement by trial and error. Workers should be fitted to their work, taught their work, clothed for their work, provided with suitable food, and stimulated to personal hygiene. Work should be fitted to the worker; ventilation made effective; lighting made adequate; tables, benches, tools, and machines constructed to suit each worker, periods of work and of rest scientifically planned. What is required is a right understanding of work in relation to the human machine and attention to this machine, its possibilities and reactions, its medical and psychological aspects. Then well-being and contentment, skill, and production will be increased, while chronic fatigue and discontent, inefficiency and poverty will be decreased.

There is no doubt that industrial hygiene is almost if not quite the most important branch of preventive medicine. In an industrial country as is Great Britain, it is the most important branch. It means everything to maintain the worker in good health and spirits and, of course, one goes with the other. Professor Collis well summarized the position of knowledge with respect to industrial hygiene of to-day, although, perhaps, he did not dwell so much on the evils of monotonous toil as he might have dwelt. A great deal of the highly skilled labor of the present time is deadly monotonous. Machines and engines constructed on the standard principle leave little to the initiative or ingenuity of the artisan. As a rule the work is the same day after day and his chief incentive is to get through as much as possible to earn big wages. Monotony of labor ranks almost with over-fatigue in its deleterious effects and should be counteracted as earnestly as over-fatigue.

As another speaker at the congress, Miss A. M. Anderson, Principal Lady Inspector of Factories, pointed out the question of industrial hygiene is international; and it may be noted that in the field of research this era is dawning, for the Comité d'Hygiène of France, the American Committee on Fatigue, and the British Research Board are in close touch, M. Langlois and Professor Lee both attending a recent meeting of the board in London.

Obituary.—Dr. Francis John Harvey Bateman died from heart failure a few days ago when about to leave his residence to take a vacation. The deceased medical man was fifty-one years of age and the son of Sir Frederick Bateman, M.D., of Norwich. He was educated at Norwich Grammar School and Pembroke College, Cambridge, and received his medical training at Edinburgh and Paris. After graduating M.B.C.M. at Edinburgh University in 1898 he held resident posts at Edinburgh Royal Infirmary and at the Leith Hospital. He took his M.A. Cambridge in 1890 and M.D. Edinburgh in 1905. For a time he resided in Paris and acted as resident medical officer to the Hertford British Hospital, and worked while there at the Pasteur Institute and at other French hospitals. Dr. Bateman was a vice-president of the Medical Society of London, a Fellow of the Obstetrical Society, a member d'Alliance Franco-Brittanique and a J. P. for the county of London. Among his appointments were those of medical officer to the Blackheath and Charlton Hospital, the Belmont Home for Ladies, the Dartmouth Home for Crippled Boys, Blackheath, and the St. Dunstan's Annex for Blind Soldiers, Blackheath.

4. Note on the Uncomplicated Fracture of the Zygomatic Arch, with Report of Two Cases. Frederick W. O'Brien.

2. Chronic Intestinal Indigestion in Children Over One Year Old.—Philip H. Sylvester confines his attention to those cases which do not digest the average amount of the average kind of suitably prepared foods. Clinical experience and opinions crystallized from the study of many cases of chronic intestinal indigestion have shown that seldom is more than one component of the food primarily at fault. It is thought expedient, therefore, to consider each component separately, and to speak of "fat indigestion," "carbohydrate indigestion," and "protein indigestion." The writer purposely refrains from mentioning the use of medicines or the active digestive substances borrowed from animals, in the discussion of the treatment of the different phases of chronic intestinal indigestion in children. There is nothing more fascinating than to watch starch fade to sugar, and meat disappear, under the action of these digestants in a test tube. There is nothing more disappointing than to see the same old food particles appear in the stools, and the same old symptoms continue, after giving children ounces of these digesting substances, even though they are chemically treated so as to be protected from the stomach juices. There is no such high road to success. *Each case must be individualized.* It is probable that all will be somewhat improved upon careful regulation of the diet based upon general principles, but few will really get well.

2. The Early Signs of Tabes.—Burton Peter Thom reminds one that tabes, like its congener, paresis, is an insidious disease. It is therefore most difficult to diagnose at the onset, but it is at this period when the damage done is still slight that it offers the best, if not the only, opportunity for arrest. One of the first of the premonitory symptoms of tabes is impotence. Another early symptom is slowness in emptying the bladder. Failing vision, which cannot be helped by glasses, or the gradual or sudden appearance of scotoma, central, homonymous or heteronymous, should always cause suspicion of beginning tabes. An ophthalmic examination should be made at once to determine the presence of choked disc, although there may be considerable choking of the disc without impairment of vision. Smallness of the pupils—spinal myosis—may precede the classic Argyll-Robertson pupils for a considerable period, and this condition of the eyes should always arouse suspicion. Diplopia or double vision is sometimes encountered in early tabes, as well as the slow and painless development of paralysis of the external muscles of the eye. A symptom which is highly suggestive of beginning tabes is loss of bone conductivity as exemplified by Egger's test with the tuning fork. It is not infrequently the very first symptom of the disease. Sudden deafness is also a sign of beginning tabes. Sudden or gradual loss of hearing in a middle aged man where no other cause can be assigned should cause a suspicion of tabes. The so-called lightning pains which are present in the early as well as the later stages of the disease are very often mistaken for rheumatism or sciatica. The character of the pains is significant. The pains of tabes are described as agonizing flashes which come and go with the rapidity of lightning. The pains of tabes are not definite in so far as any particular nerve distribution is concerned. When they leave, the skin over where the pains have been is sore and tender to the touch for some time after. Spots of purpura not infrequently follow these attacks where the pains have been. Sometimes there is a herpetiform eruption not unlike that observed in shingles. Loss of patellar reflex is one of the early signs of tabes, but the writer calls attention to the fact that the first reflex to be lost is that of the tendo achillis, or the ankle reflex. The various so-called crises are sometimes present in the beginning of the disease. Perforating ulcers of the soles of the feet, likewise, may be a premonitary sign. All forms of cardiopathies are to be noted, aortic lesions predominating. Any individual in whom tabes is suspected should have a Wassermann test of the blood and of the spinal fluid. A cell count and the globulin reaction and the reducing power for Fehling's solution should also be ascertained of the spinal fluid. Salvarsan intravenously and intraspinally in this early stage will arrest and in not a few instances cure the disease.

2. Gentian Violet in the Treatment of Purulent Arthritis.—John W. Churchman presents the histories of six cases of the three groups of arthritis (staphylococcus, pneumococcus, and gonorrheal), all acute and all purulent, treated according to the technic previously described (*Jour. A. M. A.*, April 13, 1918, 1047). He considers that the conclusion that pyogenic arthritis, due to *Staphylococcus aureus* or pneumococcus, may be cured by lavage and staining according to this method, is warranted by the facts. It is also clear that normal mobility may thus be retained. Whether the joint in this type of infection should ever be opened, unless the infection has become largely extra-articular, seems more than doubtful. The evidence for these statements, he says, while slender in quantity, is of such quality as to justify them. Concerning gonorrheal cases, somewhat more cautious statements must be made. And yet, making due allowance for the mild character of the cases treated, which were not selected cases, and for the fact that complete bacteriologic proof of cure could not always be obtained, the satisfactory clinical course warrants the belief that lavage and staining offer a method of controlling this disease. Such bacteriologic evidence as it has been possible to obtain strengthens this conviction.

4. The Value of Postmortem Wassermann Reactions.—Stuart Graves, Acting Assistant Surgeon, United States Public Health Service, states that for nearly six years the Wassermann test has been performed almost as a routine on the blood of subjects coming to necropsy in the pathologic laboratory of the University of Louisville medical department and of the Louisville City Hospital. The findings are summarized and the following conclusions drawn: 1. In ninety controlled cases there were flat discrepancies between antemortem and postmortem Wassermann reactions in only two. 2. In 124 cases showing evidence of syphilis, postmortem or clinical, 137, or 90.5 per cent., gave a positive postmortem Wassermann reaction. 3. The reliability of the Wassermann test depends to a considerable extent on the care used in obtaining and keeping the blood. 4. Cholesterinized antigens are the most delicate and do not give false positive reactions if properly used and controlled. 5. Observation of more than 15,000 reactions as correlated to clinical evidence substantiates the belief that the Wassermann test is the most delicate single test for syphilis. 6. The postmortem Wassermann test is practically as reliable as the antemortem test if the serum is properly taken and shows nothing unusual in the serum control tube.

6. The Art of Healing. Prof. A. Keith.

1. Bacterial Intoxication.—F. H. Teale discusses some recent experiments on bacterial intoxication, dividing his observations into two parts: (1) Those dealing with the bacteria themselves: (2) Those dealing with the symptomatology of bacterial infection in animals. From this study he thinks it can be regarded as probable that the toxin is apparently not due to (*a*) proteolytic degradation of the bacteria by the antibodies; (*b*) autodigestion of the plasma; (*c*) preformed spe-

cific endotoxin; but (*d*) is due to some interaction, the nature of which is as yet obscure, occurring between the tissue and to a lesser extent the free antibodies and the infecting bacterial protein; and according to the intensity of the interaction more or less intoxication occurs. The type of intoxication which suggests itself as occurring during the interaction is considered as closely paralleled by the autopoisoning produced from damaged muscles during wound shock.

4. On the Significance of Blood and Soluble "Albumin" in the Stools.—Robert Cooke holds that whenever a lesion of the alimentary canal is suspected an examination of the feces for blood and for soluble "albumin," provided the tests are adequately controlled, is frequently of immense value in diagnosis and prognosis, and may give useful indications of the progress or otherwise of treatment. The writer gives a few practical points concerning the technique and the value of the tests to the ordinary clinician, who too often wholly associates fecal examinations with complex chemical analyses only possible in a laboratory. Examination of feces for blood is fallacious unless previous diet and medication have been suitably regulated. The test for soluble albumin in the feces is probably even more important than that for blood (though both taken together are specially valuable); it indicates either failure of digestion and absorption of food albumin (a very rare condition), or the existence either of hemorrhage or ulceration of the gut. It is almost always associated with some serious condition. The presence of both albumin and blood in the stools indicates (*a*) hemorrhage with or without ulceration not very remote from the anus, or (*b*) a severe hemorrhage higher up the gut. The presence of blood alone indicates hemorrhage. The nearer the bleeding is to the anus, the less significance it has. The presence of albumin alone usually indicates serous exudation, without bleeding, probably near the anus, and presumably the further the lesion from the anus the larger the exudation must have been. More rarely it indicates a failure of digestion and of absorption of food albumins. Lavage of the large intestine, with investigation of the fluid so obtained, often gives valuable help in localizing a gastrointestinal lesion.

6. Meat Diet in Sprue. Philip Conran.

1. Diabetes in Relation to the Ductless Glands.—W. Langdon Brown advances the following generalizations: 1. The sympathetic mobilizes the sugar into the blood by means of the endocrine glands, for purposes of defence, while the parasympathetic stores it in the tissues as a reserve. 2. Ordinary diabetes shows no other signs of endocrine disease, while endocrine glycosuria betrays other evidences of that origin. 3. (1) Organic origin, with structural changes in the endocrine glands leading to (a) overaction of adrenal, thyroid, pituitary, or (b) underaction of the pancreas. (2) Sympathetic origin, with no evidence of structural changes in any endocrine gland, but producing a functional (a) overaction of adrenal, thyroid, pituitary, and (b) underaction of pancreas. Brown has long felt it a mistake to look upon diabetes merely as a disturbance of carbohydrate metabolism. But one must remember that carbohydrate represents at least 70 per cent. of an ordinary diet, and that the carbohydrates are the most readily mobilized of the foodstuffs. If the metabolism is only slightly affected, it will, therefore, be most apt to show this in relation to carbohydrates. There may be a stage in which, although the power of dealing with sugar as such is impaired, the power of converting it into fat is not. Consequently, rather than permit the escape of valuable food material, the body converts it into fat. Hence the glycosuria associated with obesity. As the disease proceeds fat metabolism is also impaired, and diacetic acid appears. Further, it has been shown that protein metabolism is involved, and even the metabolism of inorganic salts. Diabetes is, then a sign of exaggerated metabolism, evoked through the sympathetic and the associated endocrine glands, which first asserts itself in relation to the most abundant food material, but as it advances expresses itself in relation to all. The recent advance in the treatment of this disease by alimentary rest supports this view.

2. A Few Points in Relation to the Treatment of Venereal Diseases in Women.—Morna Rawlins emphasized the following points: 1. Treatment of those cases intolerant of arsenic and mercury. 2. Points in the treatment of antenatal syphilis. 3. The need of collaboration and "team work" to produce accurate figures as to the results of treatment in certain specified conditions. In the management of patients who are intolerant of treatment by arsenic or mercury the writer relies on sulphur, either alone or combined with iodine. The sulphur is given in the form of intramine, either by intramuscular or intravenous injection, or by the mouth in the form of collosol sulphur or combined sulphur. In dealing with the treatment of antenatal syphilis it is urged that cases giving a history of miscarriages and stillbirths, even with a negative Wassermann reaction, should be treated with mercury and potassium iodide. Too much stress is laid on the importance of the Wassermann reaction, and more reliance should be placed upon the clinical signs and history. Intravenous injections of arsenic can be given safely up to the end of pregnancy. The syphilologist in venereal clinics requires the cooperation of his colleagues in the eye, throat, skin, and nervous diseases departments. In treating gonorrhea in the female care must be taken that no infected part is overlooked, otherwise many disappointing results will be obtained. In ordinary subacute cases the drug treatment varies with the requirements of the individual. The most useful agents in the writer's experience have been the silver salts, such as protargol 10 per cent., eucalyptus oil in olive oil, 40 per cent., and picric acid in glycerin, 50 per cent. Many cases improve with vaccines. Skene's ducts and the ducts of Bartholin, when infected, can be fairly easily washed out by means of a syringe with curved blunt pointed needle, and if this fails the duct can be incised and treated with iodized phenol or protargol, or it can be destroyed by an electric cautery. Urethritis usually clears up readily by the application of picric acid locally and urinary antiseptics by mouth.

1. The Major Trigeminal Neuralgias and Their Surgical Treatment Based on Experiences with 332 Gasserian Operations.—Harvey Cushing, in this first paper, dealing with the varieties of facial neuralgia, describes five types of facial neuralgia capable of being mistaken for trigeminal neuralgia, namely: those ascribed to the sphenopalatine ganglion; those secondary to zoster; those attributed to the geniculate ganglion; those accompanying certain cases of convulsive tic, and, lastly, those due to an involvement of the trigeminus by tumors. There are also described what are considered

minor trigeminal neuralgias as distinguished from major trigeminal neuralgias, for which the Gasserian operation is unquestionably the proper therapeutic procedure. He points out that it is, of course, only a question of degree, but it is important to have some basis for separating them. In the case of the five types of pseudotrigeminal neuralgia which may be mistaken for trigeminal neuralgia there is every reason to refrain, if possible, from a trigeminal neurectomy.

4. A Brief Experience with Appendicostomy and Cecostomy for Intestinal Stasis in Epilepsy and Neurasthenia.—Franklin W. White has had the opportunity in the last year or two to observe a small group of patients—two with neurasthenic symptoms and two with epilepsy—who had a considerable degree of intestinal stasis and in whom appendicostomy or cecostomy was done with subsequent washing out of the large intestine for a period of six to twenty-six months. The operation was done on the theory that delay in the passage of the contents of the colon and possible absorption of toxic material was responsible for some or all of these symptoms, and that the patient would be relieved by keeping the bowel well cleaned out. All the patients were glad that the operation was done. One neurasthenic patient was definitely and permanently improved and one was not. In both epileptic cases the immediate results were fair or good (two to eight months without attacks). The late results were unsatisfactory. The writer has hesitated to advise operation in later similar cases in both groups. Constipation is so frequent in neurasthenics and epileptics that one is tempted by the theory that their symptoms are due to intestinal stasis and toxemia. On the other hand, it is too much to expect that one can change the character of these patients by operation and lavage without help on their part. One may remove a contributing cause, but not a primary one. One will always have difficulty in selecting patients for such operations, because one will often be in doubt as to which condition is primary, the stasis or the nervous condition, and one usually advises operation to break into a vicious circle and to remove a contributing cause. The question of when to close the colotomy is also difficult to decide. The writer feels quite doubtful about extending surgical treatment to any nonobstructive colon stasis case (unless there is stasis of one hundred hours or more). If he does, the operation must not be risky and must give relief without troublesome complications. Such operations are largely experimental at present.

2. Spastic Constipation.—J. M. Perret, in showing the necessity of making a correct diagnosis, if one wishes to effect a cure, emphasizes the importance of the spastic type of constipation, which is not often enough borne in mind, with the result that these cases are often missed. With the more frequent use of the *x*-ray, however, more of these cases are being discovered. When an *x*-ray examination is not practicable, in a suspected case of spasmodic constipation, the therapeutic test with antispasmodic drugs should be tried. The best of these is the tincture of belladonna. Spastic constipation may be due to marked local vagus stimulation or to an increased irritability of the neurones supplying the intestinal muscles. Reflex causes are diseases of the eye, lungs, appendix, stomach, liver, gallbladder, kidneys, etc. The stimulus is carried by means of the vagus nerve, hence the value of drugs of the belladonna group which antagonize its action. Liquid albolene is a useful adjuvant. Surgery should be resorted to when indicated.

4. Home Prophylaxis for the Prevention of Pyorrhea and Decay. John L. Kelly.

2. The Diagnosis of Internal Cancer.—Otto V. Huffman holds that in any case a patient suspected of having internal cancer should be given the benefit of: (1) A test-breakfast and gastric analysis: According to Smithies and the Mayo experience the free hydrochloric acid is diminished in quantity or absent in about 85 per cent. of the cases of gastric cancer. The Rehfuss fractional analysis of gastric secretion and the examination for occult blood in both in the expressed gastric contents and in the feces should be done. The Salomen and the Wolf-Junghans tests for serum albumen should be made. Vomitus should always be examined; blood, debris of retention, lactic acid, and Boas-Oppler bacilli, although evidence of advanced cancer naturally are of interest in making the diagnosis of advanced cancer. The feces should be examined, too; blood, pus, necrotic material—all may help in recognizing cancer, but one must not think of these as early signs. (2) A complete *x*-ray study, especially the fluoroscopic examination following an opaque meal or an opaque enema. (3) An exploratory operation if there is no restoration of health at the end of one month of symptomatic treatment, inasmuch as the alternatives from which cancer should be differentiated require operation as well and because as soon as the diagnosis would be absolutely certain it is too late to operate.

Thalamic Syndrome in Cerebral Arteriosclerosis.—Teixera Mendez relates the following case: A woman, aged 63, 15 years before had begun to show symptoms comprising hot hands (which led her to plunge the members into cold water) and a marked sense of heaviness and debility, so that work became impossible. The symptoms persisted despite all treatment, but apparently there was no marked change for the worse. The sensations became distinctly worse on the right side. The author found a woman well nourished, who walked with a gait suggesting hemiplegia. There was marked arteriosclerosis of the radials. Endocrinic disturbances were not in evidence save that the affection seems to have begun about the menopause. Neurological examination was largely negative. There were no symptoms referable to the cortex. The Babinski reflex and its variants were absent, the patellar and Achilles reflexes were exaggerated. The diagnosis of arteriosclerosis and thalamic syndrome was justified by the following: Age of patient, habit of wine drinking, slow evolution of the disease, initial disturbance of sensations of heat and weight, inability to work, insomnia, cardiovascular symptoms, hemiparetic and hemiataxic gait, spontaneous pains worse on the paralyzed side, disturbances of deep sensibility and of stereognosis. The picture differs in some respects from that outlined by Déjérine and others, as there were no choreoathetotic movements, no hemianopsia, etc., but enough symptoms were present to establish the diagnosis. The picture is by no means constant, for either sensory or motor phenomena may predominate greatly, while in other cases we may speak of a mixed type. Various authors also speak of a pure syndrome, a mixed syndrome, and a status thalamicus.

Appendicitis Season of Year and Weather.—Dubs, assistant to Professor Stahelin, refers to the antiquity of the belief that appendicitis, or as it was then called, perityphlitis, had a tendency to appear at certain seasons of the year or weather crises. Some of these were the close of summer, the beginning of autumn, and the Christmas holidays. This belief, which was held about the middle of the last century, seems to have died out completely. The author has therefore sought to submit the matter to a statistical test. Thus far we have a few statements based on statistics that the affection is more common in the summer months, that cases appear in accumulated incidence at certain periods, etc. Scattered statements are found that there is a sudden increase in January over December, that there is a

wave of increase in midsummer, that east winds and much dust favor cumulation, etc. Some Russian hospital statistics kept over a decade show maxima and minima of incidence, but these do not correspond, different hospitals showing different cumulative periods, even for the same city—Petrograd. The author consulted the figures for certain Swiss institutions and plotted curves for each year, with the result that a maximum was found to appear in March-April and minima in February, May, and September, respectively. In addition there are waves of increased incidence in the summer period, June-August and in November. These figures contradict those from other parts of Switzerland, so that mere season of year may be excluded as a general factor. There remains the possibility of a weather factor and there is some evidence that changes in the weather plays a definite rôle, together with excessive precipitation; in other words, if there is unusual rainfall plus sudden changes of temperature, we may expect more appendicitis than in dry, stationary weather.

Case of Pheochromocytoma of the Suprarenal Gland with Hypertrophy of the Left Myocardium.—Bergstrand first briefly enumerates the different forms of tumors which develop in the adrenals. He then describes a growth which began in the medullary portion of one of these bodies and consisted of polygonal epithelioid cells of variable size characterized especially by containing chromaffine collodial granules. The tumor weighed 200 grams, and lay in the upper part of the right adrenal, invested by a connective tissue capsule which included residues of adrenal cortical tissue. Despite the differences in the size of the individual cells and the disparities in appearance they were all of the same nature. Nerve elements failed completely. The cells lay in the meshes of a capillary reticulum. The larger vessels showed a peculiar build and the predominant type, the walls of which consisted of a fibrohyaline elastic connective tissue lined with flat endothelia, doubtless served as arteries. Based on a study of the finds of others is the author's opinion that the tumor was a pheochromocytoma—so named by Pick. It was a chance find in the course of an autopsy on a woman of 50, dead of influenza. The heart was hypertrophied, weighing 500 grams, as the result of notable enlargement of the left ventricle. In the absence of other causal factors for this enlargement the author is inclined to accuse a state of hyperadrenalemia due to the presence of the tumor.

Opotherapy in Pediatric Practice.—Apert refers to the experiments performed on lowly organized vertebrates in which after the thyroid body has been destroyed thyroid feeding may cause such remarkable transformations as to amount to a mutation of species. Animals in the larval state have even developed sexual apparatus the author says, and reproduced themselves as larvæ. We know less of the adrenal but in the growing subject the internal secretion of these bodies plays a role in sexual development as seen in tumors of the adrenal cortex. Young girls in such cases are transformed into pseudo-male types developing a beard, with hypertrophy of the clitoris and suppression of the menses, retraction of the vagina, and profound mental changes. They leave the sewing needle for rough boyish sports, become rough and brutal, take to tobacco and alcohol. In certain cases they develop hairiness of the chest and growth of the musculature. An anomalous feature is the development of obesity which stands in some relationship with the hirsutism. Occurring in fetal life this excess of adrenal secretion may give rise to pseudohermaphrodism of the ordinary types. In other adrenal tumors in which there is a deficiency of internal secretion progeria may develop. In tumors of the hypophysis in the young we see supervene conditions embraced under gigantism, acromegaly, and infantilism. Naturally in these conditions of excess nothing much can be done by direct opotherapy but in converse states of maldevelopment everything can be done. Thyroid feeding is indicated in practically all kinds and types of arrested development, adrenalin in asthenic and apathetic states. in all cases of excessive growth and slenderness and in feministic makeup of male youth, and pituitary extract in the broad and "stove in" types, the hirsute, and the obese.

Le Bulletin Médical.

Treatment of Icterus by Sweetened Urotropin.—Weil refers to a report made by him in 1915 on the treatment of typhoid fever by adrenalinized sugar given by the drip method. This was pronounced superior in results to the Brand method. Later the author tested the same remedy in the pneumonias. The constant drip method appeared to secure diuresis with lowering of temperature and pulse. The author has therefore made some use of the method in all infections. Among these only dysentery showed itself beyond control. Incidentally the drip method has been used in thirty cases of icterus of various types. In this affection, however, he added to the sugar urotropin and apparently omitted adrenalin. One liter of tepid boiled water received the addition of 45 gm. of sugar and 1.5 gm. urotropine. The method of exhibition appears to be the Murphy drip, which the author terms the "drop by drop" method. The amount infused into the colon is progressively increased, beginning with half a liter, increased to 2 and 3 liters in as many days. Under this management the urine clears up promptly, while the feces resume their natural hue. After the subsidence of the symptoms the drip is continued for a stated period, and despite the marked diuresis weight is gained. The superior results are naturally seen for the most part in cases of simple catarrhal jaundice, whereas in the secondary forms symptomatic of severe organic disease the benefit is only casual and may be absent outright. The author takes to himself the credit for the systematic routine use of the Murphy drip, for his predecessors, Murphy and Chauffard, used it rather for special occasions in which something urgent was demanded.

Dementia Precox and Tuberculosis.—Laignel-Lavastine has reason to believe that certain precocious dements owe their condition to a tuberculous substratum. The classification of Kraepelin naturally gives no room for this supposition, being wholly symptomatic. The older view of Morel recognized an acute dementia which particular form the author thinks he has seen in candidates for tuberculosis. It is possible that consumption masks these cases which tend to end at an early date from that disease but the author has seen dementia in fibroid phthisis as well. The cases are very complex, with history of parental alcoholism and syphilis, while clinically any of the forms of Kraepelin may be represented. Cases are cited from the writings of various alienists and from the author's own material. Thus one young man, the son of an alcoholic father who was probably also syphilitic, developed mental weakness characterized by failure to realize his condition, affective indifference, disorientation, apathy, perseveration of attitudes, grimaces, etc. He was found to have chronic pulmonary tuberculosis of the right apex. In another group were two young men, both of whom were red headed and tuberculous, who showed paranoid symptoms. In a third group the subject had tabes and amaurosis due to the same, with phthisis and paranoid dementia. Autopsy showed the coexistence of tuberculosis and metasyphilis. A fourth group was represented by a young man of phthisical habit who after a delirious episode exhibited marked mental failure. Hence the mental state which develops in chronic, nonprogressive cases and in mere candidates for phthisis cannot be due to any acute course pursued by the disease, although such a view seems to have been entertained in some quarters.

Book Reviews.

A STUDY IN THE EPIDEMIOLOGY OF TUBERCULOSIS, with Especial Reference to Tuberculosis of the Tropics and of the Negro Race. By GEORGE E. BUSHNELL, Ph. D., M.D., Colonel, United States Army (Medical Corps) retired; Honorary Vice-President and Director National Tuberculosis Association of the United States; Member American Climatological and Clinical Association. New York: William Wood & Company, 1920.

So few authoritative works have been published on this important subject that the present work by Colonel Bushnell will be welcomed by all students in our own as well as in the tropical countries. The mere enumeration of the titles of the 13 chapters will give an idea of the thoroughness with which this difficult subject has been handled in a remarkably concise and yet complete work. The chapters are headed: "The Pro-Kochian Era," "The Modern Era," "Tuberculized Races," "Non-tuberculized Races," "Modes of Infection," "Pathology and Pathological Anatomy," "Diagnosis, especially Tuberculin Diagnosis," "Prophylaxis of the Non-immunized," "Treatment of Tuberculosis in the Tropics," "Tuberculosis of the American Negro and of the American Indian," "Epidemics of Tuberculosis," "Some Practical Considerations," "Summary and Conclusions."

The book not only shows the wide reading of the author but also his own vast experience as an army surgeon. In the chapter on Tuberculin Diagnosis it is interesting to see an authority like Col. Bushnell admit its uncertainty. He says: "The cutaneous tuberculin test is of value in diagnosis if the result is a positive reaction. It is, however, likely to be negative in the class of cases which most require elucidation. The reaction is also usually negative in the cachexia of advanced disease, including tuberculosis, and is often absent or weakened in acute infectious diseases."

To the physician not practising in the tropics the subject of tuberculosis of the American Negro and the American Indian is particularly interesting and many a one will be surprised to learn that the Colonel takes exception to the oft-repeated statement in textbooks on tuberculosis that "the Negro of the United States was free from tuberculosis so long as he was a slave but became tuberculous to an alarming extent when he came in contact with civilization." One must study the preceding chapters to see the cogent reasoning for the refutation of this statement. Interesting also is the author's assertion, which is borne out by other observers, that climatic influences are negligible factors in comparison with the presence or absence of immunization against tuberculosis. A wealth of information is contained in the chapter on Practical Considerations. It should be read and reread, not only by the tuberculosis specialist but by the general practitioner as well.

In this chapter the following statement is made: "One of the most dangerous doctrines relating to prophylaxis is that good health prevents tuberculous infection. It is true, no doubt, that good health will prevent tuberculous infection from becoming tuberculous disease, but good health has nothing to do with the reception of the tubercle bacillus into the body. We have seen the evils which ensue when the consumptive comes in contact with an unprotected race." The Colonel evidently does not believe in the phagocytic property of the white blood corpuscles, the doctrine taught by Metchnikoff. It would not do to popularize this statement because the ordinary layman is not able to appreciate the distinction between tuberculous infection and tuberculous disease. On the other hand, the reviewer is delighted to see the strong and sensible directions which are given to prevent the susceptible infant and child from becoming infected by the tuberculosis carrier.

Of great interest are two conclusions in the summary of this remarkable book: "Modern civilization brings with it inevitably a tuberculization. There appears to be no escape from this without more radical changes in our mode of life than can be reasonably anticipated, so long as the cow continues to play a prominent part in supplying the daily food. There is, however, no reason for alarm in the fact that the modern world is a tuberculous world. . . . The consumptive, much to be dreaded as he is at close quarters for the uninfected, is indispensable in the present era because he unwittingly provides for that immunization which prevents our race from perishing as so many other races have perished when thrust unprepared into the midst of infection. Whether a correction is needed here because the healthy bacillus-carrier could perform this function unaided is a doubtful question, the answer to which can only be obtained by much investigation. However that may be, should we not look forward to the time when nature's methods of tuberculization, so terribly wasteful of human life, shall be replaced by a thoroughly scientific method of artificial inoculation in which no life will need to be sacrificed?"

The careful perusal of the book will repay every student of the tuberculosis problem. His views will become larger and the optimistic conclusions of the author will not leave with him an unpleasing impression but will urge him on to further investigation and study tending to help in the combat and ultimate victory over the great white plague. The book is well printed and well bound, and henceforth no library on tuberculosis will be complete without it.

DIE REIZTHEORIE UND DIE MODERNEN BEHANDLUNGSMETHODEN DES DIABETES. Von Priv-doz. Dr. R. KOLISCH. Berlin and Vienna: Urban und Schwarzenberg, 1918.

IT is Kolisch's belief that sugar is not directly utilizable in the body, but must first enter into molecular union with the protein before it can become a source of energy. Only in the disintegration of this combination is the sugar liberated in a form suitable for oxidation, and the protein component of these highly complex molecules acts as an accelerator in the combustion of the sugar. In diabetes this continuous cleavage of sugar from the protoplasm and tissues is increased through toxic or nervous stimulation so that the hyperglycemia and glycosuria are to be regarded as the results of this abnormal overproducion of sugar. On the basis of this theory Kolisch develops a highly interesting and suggestive discussion of the symptomatology and treatment of the disease, laying especial stress on the value of undernutrition and on the reduction of the protein intake. This demands a study of the nutritional requirements in each individual case, and he criticises the indiscriminate resort to starvation as a routine procedure.

DIE MEHLFRÜCHTEKUR IM DIABETES MELLITUS. Von Prof. Dr. W. FALTA. Vorstand der III medizinischen Abteilung und des chemischen Laboratorium des Kaiserin Elisbethpitals in Wien. Berlin and Vienna: Urban und Schwarzenberg, 1920.

IN this interesting volume on the use of cereals in the treatment of diabetes Falta discusses the subject of carbohydrate cures in general and describes a method of employing a mixed cereal diet which he has found valuable. Using von Noorden's oatmeal cure as a starting point, he investigated a long list of cereals in regard to their suitability for a similar mode of treatment and came to the conclusion that when used in the same way they were equivalent in effect and no less useful than oatmeal. In order to avoid the monotony of being obliged to subsist on only a single form of cereal the experiment was tried of giving the patients a mixed diet consisting of a number of cereals, and it was learned that this did not influence the effect of the treatment. The next step was to try these cereals not only in porridge form, but also to some extent prepared in different ways to make them more palatable, and small amounts of vegetables were added. Again it was found that the result was as satisfactory as before, and it is this form of the diet that is considered most advantageous by Falta. The details of preparing such a diet, the indications for its use and the management of complications are fully discussed, and the appendix to the volume contains full protocols of a large number of cases.

The questions here brought forward and discussed are all of much importance and the book deserves the attention of any physician with more than a passing interest in the treatment of diabetes.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 23, 1920.

DR. LILLIAN K. P. FARRAR IN THE CHAIR.

Bacillus Aerogenes Septicemia with Methemoglobinemia, Following Abortion.—Dr. C. S. B. CASSASA reported these two cases. He said that all cases of aerogenes septicemia with methemoglobinemia resulted from wound infection. The occurrence of this condition in a woman without obvious wound should direct attention to the uterus. Following abortion the open sinuses and the placenta offered a favorable site for the introduction of the infection through an infected catheter. In the presence of this infection there was absence of inflammatory reaction in the uterus, hemolysis occurred, and hemoglobin was changed into methemoglobin. The methemoglobin passing into the skin caused a reddish-brown, copper-colored pigmentation. This substance also passed into the kidneys and into the urine. During the change of the hemoglobin into methemoglobin there was a rapid accumulation of carbon dioxide in the blood, which explained the clinical features observed in aerogenes infection. The *Bacillus aerogenes* produced gas which was shown by the crepitation in the superficial veins. The first case reported was that of a woman, twenty-three years of age, who died seventy-two hours after inserting an infected catheter into her uterus to produce an abortion. When an infection of this nature was suspected it was important to take specimens of blood and urine for spectroscopic examination, and also to make bacteriological and cultural examinations. The organisms were found in the blood of this patient after death. There was the characteristic pigmentation of the skin, kidneys, and urine, and an increased leucocytosis in both cases.

Dr. FARRAR asked if it were possible by clearing out the uterus to increase the chances of fighting the infection.

Dr. OTTO SCHULTZ said that once the blood current was infected with the *Bacillus aerogenes* there was not much hope of being able to do anything by means of local treatment. In the case reported, the infection spread more rapidly after curettage, and a further rise in temperature and pulse rate ensued. In regard to bacteriological examination, in the case he had reported pure cultures of *B. aerogenes* were obtained from the spleen. The particular feature about this bacterium was not only the hemolytic change it caused, but the very definite change of hemoglobin into methemoglobin. Dr. Schultz cited the case of a man whose legs were crushed by an elevated train. The tissues of his legs became emphysematous, and by palpating his veins direct crepitation could be detected. The man was copper-brown and died the following morning. In a case of attempted abortion the first thing the physician should do when he saw the patient was to remove the catheter, if it was still in the uterus, and to use hydrogen peroxide. By this means it might be possible to release enough oxygen to control the *B. aerogenes* in loco. As far as the bacilli in the blood were concerned, he thought the serum Dr. Jablons had reported on should be used. The great difficulty seemed to be that by the time the infection was recognized it had advanced to a stage where antiseptic or surgical treatment no longer availed and the only hope for the patient was in antitoxin treatment. Spectroscopic examination of the urine was not simply the proposition of recognizing absorption bands, but involved the coefficient of the absorption of light in the particular band in question, so that it was a matter requiring expert knowledge. As regarded the channels of infection, the most common was through the lymphatics with general peritonitis; less commonly the infection was carried by the blood vessels and there was a thrombophlebitis. It was well to remember that women with this infection were septic and rarely showed a positive culture so far as the blood was concerned. The examination of the urine was an important point and should not be overlooked where there was a possibility of this type of infection. Other poisons like chlorate of potash, ferrocyanide of potash, nitrobenzol, antifebrin, and others were capable of producing a change of hemoglobin into methemoglobin, but they did not produce hemolysis with skin pigmentation. This pigmentation occurring so rapidly and being so characteristic was an absolutely pathognomonic sign on which the diagnosis could be made.

Dr. B. JABLONS spoke of his experience overseas with wounds infected with gas gangrene. A great many of these cases were not infected by the *B. welchii* alone, but were polybacterial infections, and it was sometimes difficult to identify the organism mainly responsible for the infection. Many people assumed that the *B. aerogenes capsulatus* was the organism that always produced gas, but cases were frequently encountered in which the effects of bacterial toxines overshadowed those of the gas. Again, many cases were diagnosed septicemia which later were found to be aerogenes infections. The question of hemolysis was important. It had been found that the *B. aerogenes* produced two varieties of toxin, one a hemotoxin which produced this lysis of blood cells, and the other a neurotoxin which was responsible for death. Against this particular toxin, hematoxin, Ford had produced an antiserum which seemed to be fairly potent. In *B. welchii* infections good results had been obtained with this antiserum, which was now produced at the Rockefeller Institute. The trouble was that they were dealing with a polybacterial infection, and while they were able to neutralize the hematoxin of *B. aerogenes*, they were unable to neutralize the others. It was only by the use of a triple antitoxin that good results were obtained. Culturally, it was possible to make the diagnosis in twelve hours after inoculation into the appropriate culture medium, if the organism was present in the blood, but sometimes it did not pass into the blood stream. Occasionally the *B. welchii* localized in a phlebitis, which could be controlled by an antiserum. Another feature of this infection was the putrid odor. For a long time it was thought that the *B. aerogenes* was capable of producing putridity, but now it was known that it did not break down protein. When the uterine discharge showed putridity this was usually due to associated organisms. These were dangerous in that they increased the virulence of the *B. aerogenes*, and this should be kept in mind in making cultural examinations.

A Case of Unusual Ectopic Gestation.—Dr. GEORGE GRAY WARD reported this case. He stated that the patient, a woman about thirty years of age, came under observation in a condition of profound shock, with all the signs of internal hemorrhage. She gave a history of spotting for five or six weeks, but suffered no pain of any particular moment. She had been going about her usual vocations and did not consider that she was sick. She had had an operation several years before at which the appendix and the right tube and ovary were removed. The onset of her illness began while she was at lunch, apparently perfectly well, when she was seized with a very violent pain in the lower abdomen, followed by immediate collapse, so that the physician thought she was about to die. When Dr. Ward saw her the pain was distinctly on the right side, which seemed strange in view of the fact that the appendix and right tube and ovary had been removed, and as the patient presented a picture of ruptured ectopic. On examination nothing definite could be made out on the left side; the right side was tender and full and there was evidently blood in the abdominal cavity. A further point of interest in the history was that the patient had had several attacks of gallstone colic definitely diagnosed as such. It seemed that the diagnosis must be ectopic, that it must be that either an interstitial pregnancy was present, or that a stump of the tube had been left which had become impregnated. The patient was removed to the hospital and operated upon. On the right side at the stump where the tube had been removed was a ruptured ectopic. There was about half an inch of the stump left, which was the seat of the ectopic gestation and had ruptured. The ovary on the right side had been removed so that the ovum must have come from the left side. The gallbladder was explored and found to be absolutely normal. The patient made an uneventful recovery.

Dr. HERMAN GRAD said that the interesting question in this case was how the ovum got into that remnant of a tube. Was it open at its end? If so, then the ovum from the left ovary had to migrate there; or did the ovum reach the tube in another way? That was an interesting question. Usually Fallopian tubes that were resected did not remain open. Dr. Grad said he had occasion to open the abdomen in several cases in which he found the free end of the tube closed. Whether that was always the case he did not know, but in three cases he could positively state that the tube was not open, and yet it was known that in many cases the tubes had become patent when they were tied off for the purpose of sterilization. Cases were reported in which the tubes were reopened after having been tied and conception occurred. Very likely in this case the tube was open, and the ovum simply remained in the remnant of the tube which had had its mucous surface damaged by a previous infection, preventing the ovum reaching the uterine cavity.

Dr. HAROLD BAILEY said that Dr. Ward's case brought to mind a case of Dr. Cole's in which a patient had an ectopic gestation in a tube and had an old ectopic near the horn in the same tube, meaning that there must have been a migration of the ovary from the other side.

Some Immediate Effects Following the Use of Radium for Non-Malignant Uterine Bleeding.—Dr. WILLIAM B. GRAVES, who was to have read this paper, was absent, but the following discussion of the subject took place:

Dr. WILLIAM S. STONE said that in thinking of this subject the first thought that came to him was the tremendous amount of pathology that the words "uterine fibromata" implied. These tumors, small and large, underwent nutritional changes and sometimes became infected so that one might meet with pyosalpinx, hydrosalpinx, and bleeding to the extent that the patients were on the verge of exsanguination. Then the thought also came that all this pathology had been revealed by the surgeon at the operating table, and not by the pathologist, and that brought one to the main thought that he wished to emphasize, which was that in the use of physical agents in the treatment of these conditions we had a terrific undertaking, as there was a great deal of pathology to be thought of. In the use of radium and the *x*-ray the first and most important thing was to establish the diagnosis—to make sure that one had a fibromyoma, and to make sure that it was not complicated by any nutritional disturbances, and that there were no collections of pus in the pelvis. In the vast majority of instances this could only be done under an anesthetic. Dr. Stone cited a case he had seen the day before which illustrated a good many points in the use of radium. This patient, thirty-seven years of age, had had a child six or seven years before without any complications at all. About a year and a half ago she began to bleed irregularly. Nothing was done until a year ago, when she was curetted. Examination of the curettings established the diagnosis as fibroid. The bleeding stopped, then recurred, and there had been more or less persistent bleeding during the past year, so that when she came under observation a few years ago, though a stout woman in good general health, she was very anemic. The blood count showed the red cells to be 2,500,000 and hemoglobin only 49 per cent. With this low blood count he was, of course, loathe to do a major operation if any other procedure would be effective. Under anesthesia it was found that the uterus was enlarged symmetrically to the size of the fifth or sixth month of pregnancy. On exploration of the interior of the uterus no particular irregularity was found. There was a small amount of smooth, grayish material curetted which was characteristic of hypertrophic endometrium. One thousand millicurie hours of radium were used. Dr. Stone said he was sure that woman's bleeding was going to stop and that the uterus would decrease in size, but he was not sure whether menstruation would stop entirely. As the woman was thirty-seven years of age, it did not make a great deal of difference if menstruation did stop. The point was that possibly six, seven, or eight months hence she might start to bleed again, and her uterus might not with this one treatment decrease in size to any great extent. If she went to another surgeon then he might operate and think the radium had been infective. Dr. Stone said if he found that a fibroid had become polypoid he would hesitate to rely entirely on radium because of the necrosis that might possibly occur in polypoid fibroids. He had seen cases of uterine cancer which had been treated both by Dr. Bailey and by himself in which complete retrogression had taken place, and there was no gross evidence of the tumor. The uterus treated by radium decreased as a rule to the size it normally was at the menstrual period, and often times at the end of a year scarcely a trace of the uterus could be found. In treating the case just referred to he used platinum over the radium, which shut out the more superficial caustic rays. If the rays were filtered in this way destruction of the uterine mucosa was not so likely to occur, and there would not be so much discharge after the treatment. Some cases of uterine fibroids treated by radium were followed by a large amount of leucorrheal discharge which was quite persistent, and it was quite an advantage to avoid that. It was extremely important to select cases carefully for radium treatment. Neither radium nor the *x*-ray was going to supplant operation *in toto*, but it was going to supplant operation in a large number of instances either as a curative measure or in temporary emergencies. The case cited exemplified this, as a hysterectomy might have been done and the patient might have recovered; at the same time, with the low hemoglobin, an operation was something of a risk, and the radium tided the patient over, so that if a subsequent operation was necessary the woman would be in better condition to stand it.

Dr. HAROLD BAILEY said he was interested in coming here to listen to the paper of Dr. Graves, because it dealt with some of the immediate effects following the use of radium. He was very anxious to hear what those effects were. One could conceive of several occurrences immediately after radiation, but they were very infrequent in his experience. In the first place, there was the possibility of lighting up an old pyosalpinx, and in his experience of five years he had had only one such case, which resulted in death, in either malignant or non-malignant uterine bleeding. That case on autopsy showed, as far as one could tell, an absolutely normal uterus; that was, the wall showed no slough or ulceration, but there was an old pyosalpinx bound up in the lower part of the pelvis and it had lighted up and the woman died of a septic infection. Another peculiar case that Dr. Bailey recalled was one in which the diagnostician had not been clever enough to exclude other conditions besides the uterine one. That was the case of a large fibroid in a woman who was very anemic, and at autopsy, after a radium application, it was found that she also had tuberculous peritonitis, and there was considerable sloughing over the peritoneal surface of the uterus and also of the abdominal wall next to the area where the applicator had been. Other immediate effects were possible, such as stricture of the uterine canal. In all their cases, over 500 in number, they had had only one such instance, and that was in a cancerous tumor of the cervix, in which there was a stenosis and pyometria. At that time the tri-weekly application of moderate amounts was used, 100 milligrams, and as he recalled it, during the third week the woman returned and the pus was evacuated. He did not recall the end results. Stricture had been guarded against, especially in those cases of fibroid where reapplication had to be made, and it was important not to put the capsule back in the same place where it had been the first time; and in cancer of the cervix it certainly was not necessary to put the radium capsule in the same area, since the capsule was only three centimeters long at the most and could be placed above or below the first point of application. If it was placed in the same spot (and he had had considerable experience in placing it in the same spot in bygone times, because in trying to get the dose out in the parametrium with the single capsule he placed them every week for three weeks in the cervix), it led to a necrosis which was very deep; it actually did, however, take the dose far out into the pelvis, but he thought it a very poor method of placing the radium. Aside from those effects, one heard occasionally of mild bladder trouble. He was discussing this with a house surgeon to-day, who said that if you asked the pa-

tients directly if they had any trouble in passing urine, they said they had none; but not a few of them, if you led up to the answer, would say that they had had some frequency. He had seen a case in which there was frequency and also pain following a very small dose placed in the body of the uterus. This woman undoubtedly did have irritation of her bladder, which necessitated treatment. Another effect which was more or less immediate was the discharge. There was for perhaps the first week a watery discharge in a few of the cases, and in not a few there was a tenacious, yellow, foul-smelling, mucous discharge which persisted for months. This was one of the meanest complications that one could have in the treatment of these fibroids, or fibrosis cases. So far as he knew, there was nothing to do for that condition. He had used douches and even intrauterine injections of argyrol, but had seen no results. These were the only immediate effects of the small doses which were used for fibroids or for fibrosis. Dr. Bailey said Dr. Stone had brought out a very important point, and that was that the diagnosis could not be made without an anesthetic. You must have complete relaxation over the whole pelvis with the woman under an anesthetic, and this was the time when the curette must be used even with the fibroid cases. One should palpate over the inside of the uterus, as there might be a polyp present, as Dr. Stone had brought out. As regarded the dose and its application, it made no difference how the applicator was filtered, providing one knew the filter and allowed for it. When platinum was used, the dose that Dr. Stone said he used yesterday—1,000 millicurie hours for a fibroid—he thought was the exact dose to bring on the menopause and to stop the bleeding. He had used in quite a number of cases a smaller dosage, with the idea that following the cessation of menstruation the menstrual periods might return after eight or nine months. In most cases in which he had used doses of 500 hours or under, the dose had to be repeated. He had one case, sent by Dr. Grad, in which the dose mentioned produced cessation of menstruation which lasted over a year. But if the filter was platinum, the dose would have to carried to 1,000 millicurie hours. If silver was used, or a combination of brass and silver, the dose should be cut down to 750 millicurie hours. These fibroid cases gave a rather peculiar history, especially as it was generally believed that the effect of radium was to kill the dividing cells in the follicular portion of the ovary, and it was rather strange that the woman was almost invariably bled at the next period after the administration of the radium. It was difficult to reason that out, and not infrequently following the administration of radium there would be a little show of blood and a watery discharge at the second period, and then there would be no menstruation for a number of months. In a number of fibroid cases irregular bleeding had started up again and he had taken out the uterus, and he now regretted it, because he found a firm, hard uterus and he felt that another dose of radium would have relieved the bleeding.

Dr. GEORGE GRAY WARD, Jr., said that he was very much interested in the immediate effects of radium. He had had the use of this agent for only a little over a year. On looking up the radium records of the Woman's Hospital, 52 cases of fibrosis uteri or fibromyomatous growths were found which had been treated with radium; these were exclusively of the malignant cases. Of these, 32 were what we ordinarily designated as fibrosis, that was to say, there were no demonstrable fibroids that could be palpated, and where there was a symmetrical uterus which in spite of curettage persisted in bleeding, and which hitherto could be relieved only by hysterectomy. Those cases were all satisfactorily relieved by radium. They had treated a number of cases of fibroids, mostly small, but there had been one or two large growths complicated by anemia where an operation was not considered advisable. In looking up the records on these 52 cases to find what the immediate effect of the radium was, it was found that 22 had pronounced nausea and vomiting, or a little over 44 per cent. Eleven of these cases had pronounced pain, requiring morphine; that was, about 22 per cent.; 18 of the 52 had no symptoms. As to the question of pain during the application of radium, one would almost suppose that the pain complained of would be due to the fact that a foreign body was placed inside of the uterine cavity, and radium, being a foreign body, the uterus would try to expel it, thus causing a certain amount of uterine colic; however, we had to bear in mind that the use of intrauterine stems in dysmenorrhea caused very little pain. In fact, he was surprised when he had a case of pain with an intrauterine stem, although it might be cast out, showing that the uterus had been contracting, yet the woman seemed scarcely aware of its presence. Therefore, it was open to question whether the pain was due to the presence of a foreign body. The question of leucorrhea was one of interest and was often a troublesome feature, due to the length of time it persisted. In their cases at the Woman's Hospital they had observed astonishingly little of that. In the follow-up clinic they rarely heard patients complain of leucorrhea. He wondered whether the reason of that was that in all the radium applications they had made they had followed the technique of Dr. Viol, the physicist of the Radium Company, which was to filter with a millimeter of brass, in addition to the silver capsule and the pure rubber protector in which the radium was encased. A number of observers did not use the brass filter, but only the platinum or silver container with the rubber cover. Possibly that was one of the reasons their cases at the Woman's Hospital had had so little leucorrhea. The point that Dr. Stone brought up was very important; that was the need of a careful diagnosis, and that one could not make it without the aid of an anesthetic. He considered that the diagnosis was not complete unless a diagnostic curettage was made. To give one instance of that: A woman had a history of bleeding for twelve to fifteen years, and an obvious multiple fibromyomatous uterus which filled the pelvis and was nodular. She had been under the care of many gynecologists and they all had diagnosed it as fibroids. In that case a diagnostic curettage was not done because the woman had a hemiplegia and her general condition was poor. She had the radium inserted into the uterine cavity without an anesthetic, which was easy to do in her case. She came into the speaker's office about four months after the application of the radium perfectly delighted that she had had no more bleeding. Examination revealed a node on the cervix, which broke down on palpation, a very evident carcinoma. The pathological report indicated that it had originated in the fundus and had extended to the cervix. The woman undoubtedly had had carcinoma of the fundus associated with fibroids. If a diagnostic curettage had been made with the first radium application, the carcinoma would probably have been discovered and they would have considered the removal of the growth before it reached the cervix, even though the woman had hemiplegia. So far as the ultimate results were concerned, in non-malignant cases, he knew of nothing that was more satisfactory.

The Balance Between the Endocrines and Each Individual Endocrine.—Dr. SAMUEL WYLLIS BANDLER read this paper. (See MEDICAL RECORD, April 17, 1920, xcvii, 16.)

Stated Meeting, Held May 18, 1920.

DR. HAROLD E. BAILEY IN THE CHAIR.

Inaccessible Vesicovaginal Fistula (Lantern Slide Demonstration).—Dr. JAMES A. CORSCADEN presented this report. The patient was an unmarried woman, fifty-two years of age, without occupation. She had passed the menopause three years before admission. Eight months before admission she had vaginal bleeding at irregular intervals, there being a pink, watery discharge, also dragging pains and increased frequency of micturition. The patient lost weight, there was no respiratory or alimentary disturbance. The woman was referred for radium treatment, and a preoperative diagnosis was made of carcinoma of the body of the uterus. A curettage was done and suspicious fragments were taken away. Radium was applied in tubes to the uterus in dosage of 1,200 mg. An adenomacarcinoma of the uterus was found at operation and a complete hysterectomy was done with double salping-oöphorectomy. The uterus was removed without dissecting the ureters. There was an irregular thick-

ening of the inner surface of the uterus due to the radium. The bladder was opened. The postoperative course was smooth, except that urine was passed by vagina. This continued until the second operation six months later. At this time a senile condition of the genitalia was found with a vaginal orifice admitting the little finger. The second operation was done in the lithotomy position with a Suchard's incision through the peritoneum. The bladder could not be freed with safety because of the adhesions between the bladder, rectum, and small intestine. Eversion was impossible. A cuff was made of the vaginal mucous membrane and the edge of the fistula was dissected off. After the operation the patient was kept in the prone position six days. The catheter was used five days. There were severe bladder spasms. In all cases of bleeding after the menopause, the possibility of carcinoma or epithelioma should be excluded.

Spontaneous Closure of a Large Vesico-Uterine Fistula.—Dr. GEORGE L. BRODHEAD reported this case. (See page 437.)

Dr. J. RIDDLE GOFFE said that he was interested in this work on fistulas of the bladder. He had had the same experience. The case was a very interesting one and very instructive. The Suchard incision was a good one in a narrow and contracted vagina. It made the tissues accessible. The closure with three layers of suture gave a good result. Years ago he thought that failures were due to the fact that there was a very small puncture hole. The vesical end of the fistula contracted very much and drew in the tissue of the vagina so that there was a crater leading into the fistula. These cases were very difficult. Results failed because the tissue was not denuded deep enough to reach the vesical mucous membrane. The method of surrounding the vaginal end of the fistula with a circular incision was advised, and then dissecting up the mucous membrane toward the fistulous canal, bringing the vesical mucous membrane into view, so that the interior of the bladder could be reached and a favorable result secured. He was not sure of the usefulness of the prone position, flat on the face. Other workers had used the Trendelenburg position in cases where the fistula was low down. This avoided passage of the urine and satisfactory results were claimed. In Dr. Brodhead's case finally there seemed to be a tearing away of the vagina from the uterus. The finger passed through the internal os into the bladder from the cervix.

Dr. HIRAM A. VINEBERG of New York said he had had experience with these fistulas and had witnessed the operation just described, which the doctor considered easy and successful and one which made the fistula accessible; still it seemed a very severe operation for something which might be done in a different way. Years ago a technique was published in the *Centralblatt für Gynäkologie*, which was hard for the operator, but easy for the patient. The patient was put in the knee chest position and the parts viewed with the Syms speculum. A small incision was made round the vaginal mucosa and sutures passed through the edges of the fistula; stay sutures were carried out through the ureter and drawn then everted. This gave uniformly good results even in cases operated on previously eight or nine times. This procedure required a good deal of technical skill, but left the woman in good condition afterward. It needed care and experience to get the parts in good apposition.

Dr. L. K. P. FARRAR said that the best plan was to cut deeply and obliquely, curving round the anus, thus avoiding the rectal structures and the vessels. It gave good healing and it was hardly possible to see the scar afterward. Did Dr. Corscaden mobilize the bladder at all?

Dr. JAMES CORSCADEN, in closing the discussion, said that the only way to mobilize the bladder was from below; it was too near the small intestine to do it any other way; that was why they used the rectum instead of everting the bladder.

Dr. H. BAILEY of New York said that he wished to speak on the supposed origin of this fistula. He thought that instead of using radiation the uterus should have been removed as early as possible after the diagnosis was made. He thought thickening was due to the radium, but the speaker did not think so, because the thickening was due to sclerosis of the vessels, leading to general fibrosis. That could not occur in a week. One might get a plastic inflammation of the uterine wall near the radium applicator, but as in that case it was near the body of the uterus it did not seem likely that it was near where the fistula was made. The closure was satisfactory. One should ask what more after removal of carcinoma of the uterus by hysterectomy? This might cure in a proportion of the cases, but not in all. Something more could be done, especially in a hospital where there were many advantages one could make use of. The repair of fistulas was a very interesting question. One saw many following radiation, but in cases of advanced cancer it was almost impossible to repair the fistula because the whole tissue of the pelvic floor was sclerotic. He had seen an interesting case in which the patient died the eighth day postoperative. At autopsy it was found that there was recurrent cancer of the uterus, not entirely removed. The first year there was absence of clinical signs, but the second year there was a well marked mass in the pelvis and bladder wall. Radiation was repeated and the whole bladder floor dropped out and a large hole was made in the rectum. This went on for fifteen months, then a colostomy was done and the patient urinated through the rectum. She became toxic and at autopsy both kidneys were found full of pus.

Dr. BRODHEAD said that if a curved incision was made round the rectum few vessels were cut, there was very little hemorrhage, and the patient did not seem shocked at all. It was important to mobilize the bladder freely from its attachment.

Dr. VINEBERG asked if he meant freeing around the fistula, and was told "yes."

Dr. CORSCADEN said that he had used the rectum and bladder instead of using the bladder on both sides. The incision only took a minute and very few blood vessels were touched. There were no important structures attached and no vessels to tie. In regard to the etiology, he could not speak with authority. They had had 300 cases. He thought the maximal irritating effect with radium was reached in ten days. He did not think this was connective tissue thickening, but it was due to radiation. They got the impression that the uterus was congested after the radium had been inserted. The bleeding was more profuse at that stage. To learn anything about the treatment of cancer took ten years.

Dr. FARRAR said her hospital experience was the same. It was difficult to operate on congested tissues. Dr. Ward had noted contraction of the fibrous tissue.

Induction af Labor by an Unusual Method.—Dr. GEORGE L. BRODHEAD reported this case. The patient was a young woman of twenty-four years, in her first pregnancy. She was suffering from supposed toxemia of pregnancy and had marked edema of the vulva, so that she was obliged to sit up in bed. She had dyspnea and was considerably distressed. She went to full term, l.o.a.; fetal heart normal. The edema was such that she could not bring her thighs together. There were signs of mitral disease and râles in both lungs. She appeared so seriously ill that it was decided that pregnancy should be terminated. Multiple punctures of the labia were made and the edema decreased. Labor pains then set in immediately after and she was delivered of a seven pound boy.

Missed Abortion.—Dr. ABRAHAM RONGY presented this communication. He said this condition was difficult to diagnose. The average woman paid very little attention to slight irregular discharges. Two things should be noted carefully: the time of quickening and the time of expected birth, but these were not usually exactly determined by the average patient, who was usually told not to worry about the matter. There was a paucity of literature on the subject, but it was an established fact that the death of the fetus took place much more often than was supposed. The term "missed abortion" could be used to describe the intrauterine death of the fetus before viability. It was often difficult to tell when death occurred. Cessation of growth was a definite sign of fetal death, the duration of the pregnancy not corresponding to the size of the fetus. If this was watched for three or four weeks, and no growth occurred, a diagnosis of missed abortion was justified. Three or four weeks later still active interference was indicated. The dead fetus could be looked

upon as a foreign body and the danger of peritonitis should be considered. The reasons for missed abortion were very speculative. Often it occurred in women of good health, and the idea that it was due to metabolic disturbance seemed to have little foundation. It was more probably due to endocrine imbalance, and physiological disturbance in ovarian function would interfere with pregnancy. Lutein extract would often carry a woman safely to term. There were three types of abortion: (1) the acute, with large blood clot and unmacerated fetus; (2) the nonacute type, where the patient complained of discomfort, spotting, and the placenta showed hemorrhagic infarcts with a macerated fetus, showing death some time before, and (3) the type where the product of conception died and was retained without symptoms, death having taken place in the fetus or the cord. Treatment should be carried out with care, as the uterine wall was friable in these cases. Catheters with packing of the cervix were indicated. Sometimes the uterus was strong enough to expel the fetus, and might do so sooner or later if left alone, still it was unsafe to leave the dead fetus there after the diagnosis was clear.

Dr. R. H. POMEROY said that he could not elaborate what Dr. Rongy had stated. He had discovered this condition in twenty-two cases. The cases were intermittent and one was apt to forget the salient points that made the diagnosis. One wondered why abortion started or why it occurred, but one must regard it as having a hemorrhagic basis—in other words, the fetus did not perish from direct damage. One could find no reason as to why the uterus should empty itself because it had a foreign body to dispose of. Such a theory had many gaps in the reasoning. One could pack the uterus with gauze, but it did not attempt to get rid of the gauze. There must be impulses that originated contraction and retraction. There might be cases in which the muscular structure of the uterus was not capable of retraction. In one patient who went for a long time after the supposed atypical fibrosis uteri developed. The speaker said he did not think he would attempt to empty the uterus in missed abortion by any other method than vaginal or fundal section. He would hesitate to add another foreign body.

Dr. VINEBERG said that a few cases were seen every year. He used to think they should be left alone. If watched carefully, usually it would be found that there was a little staining about the time the fetus died. He now agreed with Dr. Pomeroy that these cases needed surgical intervention. He had seen one case of a doctor's wife, in which the fetus had undergone degeneration. The uterus was apt to undergo fibrosis in these cases. He did not understand why the patient was asked to come back two months later for observation.

Dr. HERMANN GRAD said he had seen a few cases. He had had one case of missed abortion in which there was considerable difficulty. This was the fourth pregnancy, and the woman developed albuminuria. She began to stain. She was put to bed and the diet changed. The albumin cleared up. Examination a month later showed the uterus the same size. She felt well, but later developed pain. Abortion was advised. A well developed male fetus was delivered. The delivery was dry; there was no fluid. The ovum was intact.

Dr. BRODHEAD said that this condition was more common than was supposed. In some cases an intact ovum was found, but no fetus at all. In many cases the fetus was absorbed. In regard to operative interference, most cases would take care of themselves. Most cases would come away spontaneously if given time. He had been looking for a long time for a calcified fetus, and would like to see one.

Dr. ALLEN said he had not heard a paper on this subject before, although the occurrence of such cases was fairly common. He felt they should all reach the same conclusions as Dr. Rongy, who had had remarkable results. There were no failures in delivery by catheter and no bad results. There was one reason for operative interference. The woman should feel there was something wrong. The periods were missed and the patient would worry as the months went on, and for this if for no other reason interference should be made. No doubt may cases were curetted before the gynecologist saw them.

Dr. BAILEY said that he had had two cases on the Bellevue service. They were not listed under missed abortion, but as death of the fetus. This term applied to the later months of pregnancy. They were all indebted to Dr. Rongy for offering something to fall back upon. These cases were seen every year, and the family usually hesitated to have any interference. In one case seen at the prenatal clinic there was a 7½ months' pregnancy, with the fetus at the umbilicus. A bag was inserted and a macerated fetus delivered without difficulty. No etiological factor could be determined. In one patient, a doctor's sister, who had numerous consultations, was supposed to be at term, the pouch was put in and in seven hours an intact ovum and sac was expelled, filled with foul smelling greenish material. It was preferable in such a case to induce labor. He thought there was a distinction in the terms of missed abortion and death of the fetus; the latter term should be used after viability.

Dr. L. K. P. FARRAR said she had seen one case in which the patient went to the seventh month and was feeling well; then there was a cessation of fetal movement. At the ninth month examination showed a macerated head.

Dr. RONGY, in closing the discussion, said that he disagreed with the advocates of surgical procedure. He had never used anything but the catheter, and he did not remember failure in a single case. Occasionally it was necessary to use it a second time. He used a large rectal tube inserted up to the fundus. Dr. Vineberg was right when he said there was a spotting at the time the child died. An intelligent woman would notice it and tell the doctor, but an unintelligent one would not. Dr. Grad asked why the uterus failed to expel the fetus, but it was not known why; it had never been explained. Toxemia might be the cause of the death of the fetus; it was found that nephritics did not respond to labor induction. He did not believe the cases should be let alone. He had the patients come for routine examination (not vaginal) every two weeks. There was no reason for leaving a foreign body in the uterus. There was very little in the literature. Cases were not studied very carefully. He thought the pathology lay in the fetus and cord and not in the placenta. Regarding the title "missed abortion," he thought it was better than "death of the fetus." The child had been growing and stopped growing and yet there was failure to abort.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 8, 1920.

DR. CHARLES HENDEE SMITH IN THE CHAIR.

Direct Laryngoscopy in Young Children.—Dr. HENRY LOWNDES LYNAH gave a lantern slide demonstration showing the picture presented by laryngoscopical examination in various throat affections in children, and emphasized the advantages of such an examination from the diagnostic standpoint.

Nephrolithiasis in a Girl of Three Years.—Dr. MINER C. HILL and Dr. A. R. STEVENS reported this case which occurred in a little girl, three years of age last November. She had had none of the diseases of childhood and had been perfectly well until she was two years old, when she was not very well and was treated by a pediatrist. He found nothing out of the way except pus and bacilli in the urine. She was treated with alkalies, but with what result they did not know. Last June the child came under Dr. Hill's care. He found that she still had pus and bacilli in her urine. For about two months she was treated with alkalies, then with acid sodium phosphate and urotropin. These remedies seemed to make no impression on the condition. Dr. Stevens was then called in. As the little girl was quite well otherwise, they deferred investigation until last fall. At that time a radiograph was taken which showed numerous calculi in the left kidney. The right kidney at first showed a suspicious shadow, but no stones were found on further examination. Early in January a double ureteral catheterization was done under gas oxygen. A No. 5 cystoscope of French 18 caliber was used and specimens obtained from both kidneys. An intravenous injec-

tion was given to test the function of the kidneys. A wax-tipped catheter was passed up to the right kidney and there was no scratch on the catheter. The right kidney, from the tests made, seemed to be normal. From the left kidney pus and gram negative bacilli were obtained. The urea from the right kidney was 1.2 per cent. and from the left 0.4 per cent. There was about three times as much phthalein from the right kidney as from the left. Inasmuch as there was pus in the left kidney and not in the right, it was deemed advisable to do a nephrectomy. There were six or eight stones present, and even if one removed all these stones and left an infected kidney there would be danger of the opposite healthy kidney becoming infected. Dr. Holt and Dr. Blake, in consultation, agreed that a nephrectomy was indicated. On January 25 this operation was performed by Dr. Stevens, removing a pyonephrotic kidney. The largest stone and one smaller were left in the specimen. Practically all the calyces were occupied with granular masses composed of one-half phosphates and one-half uric acid. On the fourth day following operation the urine was clear and free from pus and bacilli, and had remained so since. Dr. Stevens said one did not hear much about surgical conditions in the kidneys of children, and both Dr. Blake and Dr. Holt said they had not seen a case just like this one. Of 320 cases of kidney stones in children (one-half of these were autopsies) 140 were found in children under one year of age, and only 26 in children from one to six months old. When renal calculi were present in babies, the supposition was that the babies usually died. The writers wished particularly to call to mind the fact that surgical conditions occurred in the urinary tract in children oftener than we thought, and to suggest that if, after two or three months' treatment by ordinary methods, pus could not be made to disappear from the urine it was well to have these cases investigated in order to more carefully locate the source of the pus.

The Suboxidation Syndrome in Childhood.—Dr. CHARLES GILMORE KERLEY and Dr. LOUIS BERMAN presented this paper. They stated that the condition which they had designated as the "suboxidation syndrome" was found with few exceptions in the offspring of the well-to-do. The forebears of children presenting this syndrome were usually those who had lived indoor occupational lives for two or more generations—those who had been occupied with intellectual pursuits and not with manual labor. The child with the suboxidation syndrome was one whose physical functions were habitually below normal. There was a lowered capacity for endurance and his emotional control was defective. As a rule the child was precocious and mentally overactive. There was a tendency to erythema, mild eczema, perspiration was scant, low temperatures were keenly felt. A moderate anemia was felt in most cases. A frequently encountered feature was a tendency to febrile rhinitis and bronchitis. It was rare to find a patient of this type who had not had tonsils and adenoids removed with little or no benefit. Another feature of this syndrome was a tendency to recurrent vomiting. Not all cases showed the identical train of acute manifestations, but in one respect they were very similar; they had a defective metabolism for the hydrocarbons, particularly for cows' milk fat in the amount that they had accustomed themselves during the last few decades to give children. A series of illustrative cases was cited showing that the noteworthy feature in nearly every case had been the improvement in appetite and the marked gain in weight as soon as the fats and sugars which had been given above the capacity of the patient had been removed from the diet. An examination of the urine in a certain percentage of these cases showed a slight but constant acetonuria on an ordinary diet, and those subject to attacks of vomiting showed marked acetonuria during the attack. A study of the blood in a series of 67 cases had shown a hyperglycemia varying from 130 mg. of glucose per 100 c.c. of blood as the lowest, to 280 mg. per 100 c.c. as the highest, the average being 163. The blood sugar of 92 children not belonging to this group was examined and found to vary between 80 and 125, averaging 105. The method used to determine blood sugar was an adaptation of Benedict's modified picric and picrate method to finger blood along the lines followed by Epstein in applying the original picric acid method.

Dr. HERMAN SCHWARZ said he had seen many patients with the syndrome Dr. Kerley described who had eaten very little sugar, and quite a number of cases coming under his observation had not responded to reducing the sugar as such. Personally, he did not see how it could relieve the condition simply to withhold sugar, if the children were having bread and cereal, though there might be an easier absorbability of sugar. When Epstein brought out the modification of the Benedict method of estimating blood sugar, the speaker had made a great many examinations, especially in cases in which there seemed to be intolerance of sugar as shown by an increased number of movements. In these cases he found the blood sugar in the early morning before breakfast perfectly normal. In cases of eczema and so-called exudative diathesis blood sugar was not regularly increased. He had plotted the sugar curves and could not see any difference in the reaction of the blood sugar in these children as compared with normal children.

Dr. HENRY DWIGHT CHAPIN called attention to the fact that in the paper recently published in the *American Journal of Diseases of Children* it was shown that in quite a number of cases hyperglycemia occurred with little or no glucosuria. In the line which Dr. Kerley had studied much might be learned from examinations of the blood. One point mentioned by Dr. Kerley might be given more emphasis, namely, that many tonsils and adenoids had been removed that need not have been removed on the assumption that the troubles of which the child was complaining were due to that source, when, in fact, they were quite often caused by faults in the metabolism or in feeding. He was glad that Dr. Kerley had brought out that point.

Dr. BERMAN said that in reference to Dr. Chapin's remarks, they were interested to see the figures of Dr. Chapin and Meyers, published in the American Journal of Diseases of Children, showing a hyperglycemia in children suffering from recurrent vomiting. They were published when Dr. Kerley and he had practically completed their studies, and they confirmed and were in accord with their own results. However, they were practically all obtained in institutional children. It should be emphasized that their studies were made in private patients, under the conditions of everyday life. Institutional life meant a definite and abrupt change in the régime of the child which must reflect itself in its metabolism. The two sets of results were, therefore, not strictly comparable. The same comment applied to what Dr. Schwarz had said regarding his work on the blood sugar in cases of sugar intolerance. Besides, sugar intolerance and the suboxidation syndrome were not necessarily synonymous. Then he employed Epstein's method, whereas they had used, on the advice of Dr. Benedict, a finger blood modification of Benedict's revised picric acid and picrate method. The figures they obtained with their controls in 92 cases of the most varied conditions, varying between 80 and 125 mg. per 100 c.c. were absolutely comparable with those obtained when one used larger quantities of blood. The only other criticism possible of their results was their relation to meal-time. These determinations were made in the afternoon, at least two and one-half, and in most four or five hours after lunch, which as far as carbohydrate was concerned was the lightest meal of the day for these children. In view of these facts Dr. Schwarz's results could not be compared with theirs. A question had been asked about the relation of the caloric values of the children's diets to the suboxidation syndrome. They had not gone into the question of the exact caloric values of the diets, but it was obvious from the dietetic schedules that the children were being calorically overfed on the foods of the highest caloric value, milk, milk fat and cane sugar. It might be interesting to go into the evidence that justified the use of the term "suboxidization syndrome." The earliest metabolic study of recurrent vomiting, the typical symptoms of the syndrome, was made by Holt sometime in the nineties. He showed that at the height of the attack there was an increase of some

200 to 400 per cent. in the amount of uric acid excreted, corresponding to that found in the crises of gout. Then Rachford of Cincinnati showed a marked increase in the paraxanthin and heterxanthin bodies of the urine in the attack, and he had put down this as well as the increase in uric acid to a break in the chain of oxidation of the nucleic acid molecule. Then Howland and Richards redirected attention to the importance of the suboxidation of the carbohydrate molecule by their finding of lactic acid in the urine at the height of the attack, later confirmed by Underhill and Steele—lactic acid having been definitely established by Lusk as a product of the break in the chain of oxidation of glucose in the organism. They also showed in experimental animals, poisoned by cyanide and chloroform which interfered with body oxidation in general, that with general symptoms of intoxication, including vomiting, there occurred in the urine lactic acid, and an increased neutral sulphur, that was to say oxidized sulphur. Finally Sedgwick of Minneapolis and Mellanby of London showed that at the height of the attack an increased creatonuria, creatin and creatin metabolism did not belong to the realm of certainties, and definitely demonstrated conclusions, but that there was a relation between an increased creatinuria and interference with the course of carbohydrate metabolism many investigators agreed. All the evidence pointed to a suboxidation occurring at least paroxysmally in these children. Their work showing the existence in them of a hyperglycemia when apparently well, proved that there was in them a continuous disturbance of metabolism, which went on to crisis. The fact that between attacks there was a hyperglycemia, was interesting as pointing possibly to the biological value of the attack as an attempt to get rid of suboxidation products. A synthesis of all these findings had been attempted in the term "suboxidation syndrome."

Frozen Milk.—Dr. HAROLD RUCKMAN MIXSELL presented a résumé of the literature on this subject from which he drew certain conclusions. He stated that during the past three years, and particularly during the severe winter of 1917-1918, he had been asked repeatedly by patients about frozen milk and as to whether its use was harmful in infant feeding. In some instances milk delivery was prevented for two or three days by snow drifts, and was accordingly four or five days old when used plus having been frozen. At that time, and indeed ever since, Dr. Mixsell said he had advised against the use of this milk, although he had only a precedent to go by. A review of the literature showed a scarcity of material on this subject and also a confusing difference of opinion about various points which still remained to be cleared up. The first record of the use of frozen milk in commerce which the writer had found in the literature was contained in an article by Duclaux, written in 1896. Duclaux admitted that milk delivered in cold countries in a frozen condition had a changed taste, without the ordinary flavor, and that there was less cream. He believed, however, that with the aid of refrigerating machines these difficulties were not insurmountable. After making analysis of the upper and lower portions of cakes of milk frozen almost instantaneously by the method described by Duclaux, this authority concluded that if frozen milk were allowed to thoroughly melt, and if it was mixed to insure its homogeneity, no particular change in the taste occurred. He found the milk in the upper parts of the cakes more dilute and that in the lower part more concentrated than the original whole milk. C. Mai (Molk. Zeit., Berlin, 191.2 22-No. 18, pages 207-208) obtained rather similar results to those of Duclaux. The bacterial changes that occurred in milk at low temperatures had been studied by various investigators. Among these Pennington (*Jour. Biological Chemistry*, 4-1908, et ibid 16, 1913-1914) conducted experiments upon certified milk and ordinary market milk, the two being run side by side and the results compared. It was found that the bacteria increased markedly in numbers *after the first 48 hours*. Bacterial growth at the end of a week, even in the cleanest milk which contained 300 bacteria to the cubic centimeter, was pronounced. After six weeks it often passed the billion mark per cubic centimeter. In spite of the freezing an enormous increase in the bacteria occurred, and it was found that there was neither odor nor taste to indicate that this had happened. Another interesting point was that the milk did not curd even on heating, and it was not until the putrefactive organisms had multiplied that its use to the casual ooserver was contraindicated. A classification of a chemical basis of the organisms occurring at these low temperatures showed that there were constantly present bacteria which formed acid, and bacteria which acted on proteid. There were also neutral organisms which formed neither acid nor alkali and did not act on gelatin. The acid forming organisms were generally in relatively smaller numbers than were found when milk was kept at higher temperatures, and the liquifying organisms were more numerous. Certain species, such as *B. fornosus*, *R. solitarius* and *B. Ravenel* were especially resistant to cold. Coincidentally with the bacteriological study of milk samples there was made a chemical analysis of the changes occurring in the protein. This showed that the casein was rapidly digested and finally more than 50 per cent. of it was changed to soluble compounds. Caseoses, amino-acids, and probably peptones, increased rapidly at the expense of the digested casein. This was pronounced at the end of two weeks. In more recent experiments Pennington had come to the conclusion that the proteolysis of the casein was primarily of bacterial origin, and that the proteolysis of the lactalbumin was due, primarily, to the native enzymes of the milk. They also determined that milk enzymes and the bacterial flora combined, gave rise to more rapid proteolytic changes than were produced by either agent alone. This involved a breaking down of the true proteins and their passage through peptone and caseose to the amino-acids. The determination of the acidity by the $\frac{N}{10}$ sodium hydrate- phenolphthalein test showed that there was a much higher acid content after two weeks than is ordinarily required for curdling—which seldom happened. Milk having this high acidity, even when placed in an ordinary ice-chest, did not curd even when exposed to higher temperature. In regard to the effect of extreme cold on the carbohydrate constituents of milk very little was konwn. That there was some change was indicated by the quite marked increase in acidity which had been determined by the $\frac{N}{10}$ sodium hydrate-phenolphthalein test. Hepburn had also shown that the lactose content decreased after milk had been frozen. Pennington also conducted a series of experiments on the fat content of frozen milk. She found that the iodine number and the index of refraction of the butter fat remained unchanged, while the Reichert-Meissel number showed no marked change. All the progressive changes noted were caused by the vast increase in bacteria, and were accompanied by the progressive lowering of the freezing point of the milk. In regard to the action of frozen milk on the digestion of an infant or a young child there was a wide divergence of opinion. There should be no reason for the belief that frozen milk elaborated toxic substances which would disagree with the average bottle-fed baby. Kerley spoke in his text-book of having fed many thousand quarts of frozen milk to infants under his care during the past 30 years. The crux of the whole matter seemed to be in insuring the homogeneity of the milk by properly melting and mixing it before it is used. Heineman, however, said that under no conditions was thawed milk exactly the same, in every respect, as unfrozen milk. This, he stated, was due to the fact that the water froze at first at the outside on the wall of the vessel; the solids were forced towards the center, the fat rose and was partially churned when the milk froze. The natural emulsion of fat was never completely restored after thawing, and the casein appeared in flakes rather than in the original collidal condition. The emulsion of fat was destroyed more rapidly than the colloidal condition of the casein. It was probably on account of this that thawed frozen milk might decompose more rapidly than normal milk. It was therefore essential that it should be used immediately if at all. Rosenau also stated

that "Milk cannot be preserved indefinitely simply by the use of cold, since even at freezing some of the bacteria continue to grow and multiply, and putrefaction slowly takes place." . . . for freezing might alter its composition and render it undesirable. The essayist stated that owing to the marked differences of opinion, he had made it a rule in the past to advise the use of either dry milk or unsweetened condensed milk in cases in which the milk has been frozen, especially among young children. He had heard indirectly of cases of severe diarrhea following the use of frozen milk and it was on this account that he recommended the above milk preparations as alternatives. Owing to the divergence of opinion it was better for the pediatrist to substitute a temporary formula of either dry milk or cendensed milk for milk which was frozen, especially in feeding young children.

Dr. HERBERT B. WILCOX recalled that some years ago attention had been directed to this subject and a number of cases reported in which the trouble was believed to be due to frozen milk. Dr. Talbot of Boston had reported twenty or thirty cases, and spoke of the effect of frozen milk as being constitutionally depressing rather than as producing a definite type of intestinal lesion. At Bellevue they had quite a number of cases of gastrointestinal disturbance during the winter, and in investigating the cause found that the milk they had been getting had been frozen in the cans. There were forty-six children affected, varying in age from a few weeks to several months. All but seven of these, before taking the frozen milk, were non-complicated feeding cases. The majority of these children were getting raw milk mixtures, some were getting raw skimmed milk, a few were on boiled milk and a few on Eiweiss milk. Some were taking milk with a high fat content and some were taking fat-free milk. In this series of cases two facts stood out most prominently: one was that the thirty-six children who were worst were the ones taking the whole milk unboiled. Those who were least affected were the ones taking boiled skimmed milk. The most striking symptom in these cases was the appearance of the stools. Diarrhea was present which varied in intensity from two to three to eight or nine movements a day. The stools were light green, non-homogeneous, and covered with a thick layer of mucus. They were all alkaline. Over one-half the children vomited their food and afterward continued to try to vomit until the next meal. The loss of weight was striking. Three of the children in this series were severely depressed and one died. No study of the milk was made except to find the bacteriological count, and that did not vary much from the ordinary count. It seemed that freezing produced a definite effect on the milk so that it caused vomiting and a peculiar intestinal toxemia. From these observations it seemed possible that there was some change in the fats and also in the casein.

Dr. CHARLES GILMORE KERLEY said he thought there was no doubt whatever that a substance as delicate as milk must be influenced by freezing. Dr. Wilcox's observations were very interesting, but the condition of the milk before freezing was not known. It was possible that some other factors besides the freezing might have been involved. The fact was that very little milk reached the city between January 1 and March 1 that had not been frozen before it reached the consumer. Hence it seemed to him that if frozen milk was much of a factor in producing intestinal disturbances in children we would see many more cases that could be traced to this source than we did see. However, they were very much indebted to Dr. Mixsell for having made a study of this subject, and he would be glad to use his work for reference.

Dr. SMITH said it seemed that there were two things pretty definite about frozen milk: First, that some frozen milk certainly poisoned some children and, second, many children took it without any apparent ill effects. It had been his experience that after a cold snap he always received a good many telephone calls from mothers who reported a gastrointestinal disturbance after using frozen milk. If the children were put on barley water the condition cleared up in twenty-four hours. It was well to bear in mind that a great many things might happen to milk as the result of freezing and to have milk boiled after it had been frozen and where there had been undue delay in delivering it. It was not uncommon during a cold snap to see bottles of milk bearing a three-day old label, and that might be one factor in producing results that had been attributed to freezing. There had been some study of what happened to milk that was frozen and thawed, but not of what changes took place when it was frozen and thawed and again frozen and thawed out. Was it not possible that freezing changed the inhibiting qualities to bacterial growth and that milk that had been frozen became toxic more quickly after being thawed than did that that had never been frozen and thawed? It seemed that boiling the milk after it had been frozen did detoxicate it. At the time they had that epidemic at Bellevue they were using Grade B. Milk in cans and that might not have been as good milk to withstand the effects of freezing as some other milk.

Dr. ELIAS H. BARTLEY asked about some cream kept three or four months in cold storage, whether that was known to poison anybody. In April and May when milk was abundant the cream was separated and placed in cold storage. It was not frozen but was kept very close to the freezing point. It was true that such milk and cream did sour very rapidly after being taken out of cold storage. Dr. Bartley said it had once been his duty to investigate a case in which ice cream had caused wholesale poisoning. He found one particular can from one particular farm which had been kept back over two weeks. This was kept in spring water and evidently in this case the long keeping had produced a change in the cream. When kept in cold storage cream did not become poisonous and he judged from what the reader of the paper said that the casein must be changed—that a proteolysis took place, altering the protein constituents. If at the end of two weeks there was a development of amino-acids sufficient to be detected by chemical tests at the end of three months there must be quite a considerable change of that kind in the casein, yet if this was so it was rather surprising that we did not see more cases of gastrointestinal disturbance due to the consumption of such cream.

Dr. J. FINLEY BELL said that it was not so much a question of chemistry as of bacteriology. The lactic-acid producing bacteria were destroyed and spore-bearing organisms left unharmed.

Dr. MIXELL, in closing, said he had nothing to add. He had simply endeavored to review the literature, he had had no experience on the clinical side of the question. He believed it better however, to play safe and to give some other form of milk rather than that that had been frozen. The age of milk and the duration of the freezing were factors to be considered. The concensus of opinion was that milk should be used within forty-eight hours, because up to that time there was no bacteriological change, but after that time there was an increase in the bacteria, and putrifying bacteria increased very rapidly. Putrefactive bacteria were a great factor in the decomposition of milk that had been frozen.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

FLORIDA STATE BOARD OF MEDICAL EXAMINERS.

Jacksonville, June 14, 1920.

(*Concluded from page* 378.)

SURGERY.

(Answer *ten* questions only.)

1. Give differential diagnosis of coma from injury, alcoholism, opium poisoning, apoplexy, and uremia.
2. Define thrombosis, phlebitis, varix. Give causes for each.
3. Give diagnosis and treatment of Pott's disease.
4. Give etiology, symptoms, and treatment of osteomyelitis.
5. What is shock and how would you combat it?
6. Give differential diagnosis between fracture of neck of humerus and dislocation of shoulder joint.

7. (*a*) Describe Colles' fracture; (*b*) Give treatment.
8. (*a*) Give constitutional effects of burns; (*b*) Give treatment.
9. (*a*) Give differential diagnosis between acute appendicitis and renal colic; (*b*) Describe operation for removal of appendix.
10. (*a*) Give causes of intestinal obstruction; (*b*) Give symptoms of intussusception and its treatment.
11. (*a*) Give the most common varieties of fistula; (*b*) How would you operate for the radical cure of complete fistula in ano?
12. (*a*) What are the indications for enucleation of the eye? (*b*) Describe the operation.

ANSWERS.

SURGERY.

1. The following table, from Eisendrath's *Surgical Diagnosis*, gives the diagnosis:

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal, and full.	Pulse rapid, may be irregular.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow —may be 6 to 8 per minute.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.			

2. THROMBOSIS is the coagulation of the blood in any part of the circulatory system. *Causes:* Changes in the vessel walls, such as injury, inflammation or degeneration; changes in the blood; and diminished rate of the blood stream.

PHLEBITIS is inflammation of the wall of a vein. *Causes:* Injury or pressure, thrombosis, inflammation, microorganisms.

VARIX is a vein which has become permanently lengthened, dilated and more or less tortuous. *Causes:* Weakness in the wall of the vein, irregularity in the arrangement of the valves, prolonged standing, severe exertion, wearing of tight garters, pressure, heavy lifting, strains.

3. *Pott's disease of spine:* "There are three typical signs: pain, rigidity, and deformity; and there may be abscess and paraplegia. Rigidity is the most important of these signs. 1. *Pain.*—In the early stages it may be only of an aching character. Local pain is that felt in the situation of the diseased bones, and tenderness may be elicited by percussion over the spinous processes. Referred pain is produced by pressure on the roots of nerves in the intervetebral foramina, and is felt at their cutaneous terminations. If in the lumbar region pain may be felt in the legs; if in the dorsal region, pain may be felt in the abdomen, chest, or arms; if in the upper cervical region, pain may be felt over the upper part of the chest or back of the head. 2. *Rigidity* is invariably present. In the early stages it is due to muscular contractions to steady the painful part. In an adult it can be demonstrated by getting him to go through various movements while a hand is kept over the suspected area. The limitation of movement is better felt than seen. In a child, it is better to lay it on its face and test the flexibility by grasping the ankles, and so raising the legs and pelvis. If rigidity is present, the whole body is raised instead of the back being curved. In the later stages, when repair has taken place, the rigidity is due to bony ankylosis. Secondary curvatures restore the upright position of the body. 3. *Deformity* is due to falling forward of the upper part of the spine as the vertebral bodies become destroyed, so that cases cured in the early stages present none. Where only two are involved the deformity is angular; where a large number are affected the deformity is a curvature. When the curvature is in the dorsal region, the sternum becomes convex anteriorly, and the intercostal spaces are diminished or obliterated."

"*Treatment* consists chiefly in immobilizing the spine and taking the weight of the body from above the seat of disease by some form of support. The various methods are:

"1. *Rest.*—The patient should be kept on his back on a firm mattress, but never in the prone position, with firm sand-bags on either side to steady the body or neck, according to the seat of disease. If necessary, a plaster, poroplastic, or leather and steel jacket may be applied. Extension applied to the head and legs is of great value in the progressive stages.

"2. *Spinal Supports.*—So that patients may get about when the disease is quiescent, a support is necessary; children, however, require an apparatus which allows them, though still recumbent, to be carried out into the fresh air and sunshine. 1. *Phelps' box* is a wooden trough for the body, with two trunks running off it for the legs. The child is strapped into this, and kept there for two or three years, except when being washed. 2. *Double Thomas's splint:* This may be made with a head rest, to take off the weight of the head. 3. *Jackets* are used when the child is practically well. In adults they may be used after the first few months of rest. The jackets may be of plaster, poroplastic, or leather and steel. If the caries is in the cervical region, a jury-mast should be added, with chin and occiput straps to support the weight of the head. The apparatus should be worn for at least a year after recovery is apparently complete. The general treatment consists of good feeding, tonics, fresh air, and sunshine. Forcible straightening of deformity is not to be recommended."—(*Aids to Surgery.*)

4. *Acute infective osteomyelitis.* Causes: The general vitality is lowered, and there is some focus of ul-

ceration in the mouth or throat, by which organisms enter and circulate in the blood. All that is now necessary is that some part of the bone should have its vitality depressed by a blow, strain, or exposure to cold, and the organisms then attack it. The bacteria most commonly found are the staphyloccocci, but streptococci are present occasionally. The disease usually begins in the new growing bone at the end of the diaphysis, rarely in the epiphysis. The lower ends of the femur and radius, the upper ends of the tibia and humerus, are the commonest seats.

"*Symptoms.*—The disease begins with a rigor, high temperature, and severe pain. The part becomes swollen, infiltrated, and congested, with distended veins over it. The pulse is rapid and small and the tongue dry, and delirium soon comes on. It should be distinguished from acute rheumatism by the fact that the interarticular and not the articular region is affected. Fluctuation can be detected if the bone be superficial, or the abscess may burst on the surface. The bone is then found to be bare over the extent of the abscess cavity. When the bone is deeply seated or the disease confined to the medulla, the swelling is later in evidence, but the pain and toxemia are very severe, and the patient may die from this before local signs show themselves. When the epiphysis is attacked, septic arthritis often quickly follows, and a loose flail joint may result.

"*Treatment* must be very prompt. A free incision must be made through the periosteum and the pus evacuated. In any case, whether pus is found or not, the surface of bone must be gouged away to expose the medulla freely, and any gangrenous tissue scraped out. The cavity must then be washed out and freely drained. The wound in the soft structures is not closed in any part. If symptoms of pyemia occur, it may be necessary to amputate the limb through the joint or bone above, so as to cut off the source of emboli. When a large portion of or the whole diaphysis is necrosed, there are two courses; either to cut short the disease by removing the dead portion at once, or to leave the sequestrum to stimulate the formation of an involucrum. Where there is a single bone, as in the arm and thigh, the sequestrum is left; where there is a double set of bones, as in the forearm and leg, the sequestrum is removed at once. Celluloid, zinc, and ivory rods have been inserted to stimulate osteogenesis. In most cases it is doubtful how much bone is actually dead, so that it is better to open up the cloacæ in the newly formed involucrum to remove the sequestrum. The cavity heals by granulation."—(*Aids to Surgery.*)

5. *Shock* is the name given to a sudden and general depression of the vital powers due to some strong stimulation (such as injury or emotion) acting on the vital centers in the medulla, and producing vasomotor paralysis.

Treatment of shock: Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant and give a hot saline infusion; morphine hyperdermically, may be necessary for the relief of pain. Adrenalin solution is administered into the arterial system.

In surgical operations *shock may be largely prevented* by reassuring nervous patients, keeping the patient warm, the avoidance of the excessive catharsis and semi-starvation that often prevail before operations, and administration of strychnine and atropine before operation, the avoidance of delay and undue handling of parts during the operation, prompt checking of hemorrhage, and by using the utmost gentleness.

6. In *fracture of the surgical neck of the humerus*, the head of the humerus will be found in the glenoid cavity, but it will not rotate with the shaft; the arm will appear shorter; and crepitus and abnormal mobility will be elicited unless there is impaction.

In *dislocation of the shoulder joint*, the glenoid cavity will be empty, and the head of the bone will be found in an abnormal position; the arm will appear longer; there will be no crepitus, and no abnormal mobility.

7. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backwards and upwards, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking-hands" grip, extending and adducing the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later the end of the first week, to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery.*)

8. *Constitutional Effects of Burns:* "1. The symptoms of the first stage are intense pain, and shock varying with the extent and severity of the burn.

"2. If the patient survives the shock, fever develops, due at first to the absorption of toxins, the result of destruction of the tissues, and later to the suppuration which follows. There is a marked leukocytosis and polycythemia, and an increase in the coagulability of the blood, which sometimes leads to extensive thrombosis and subsequently to embolism. The internal organs in a severe burn become congested, and actual inflammation of some of the viscera may ensue. Congestion of the brain or lungs is not infrequent, but the viscera most apt to be affected are the kidneys, giving rise to albuminuria and decreased quantity or even suppression of urine, and the gastro-intestinal canal, causing vomiting and diarrhea, and later ulceration, especially in the duodenum (*Curling's ulcer*). Duodenal ulcer is supposed to be due to the irritation of toxin laden bile; it has the same symptoms and treatment as that due to other causes. Delirium or convulsions may occur from congestion of the brain. During this stage, which lasts from two to five weeks or longer, there is active suppuration with the separation of sloughs.

"3. During the stage of repair there may be no constitutional symptoms except, perhaps, weakness or anemia, unless the wounds are very large and freely suppurating, when there will be some fever (hectic), and possibly amyloid disease if the suppuration persists for a long time." (Stewart's *Manual of Surgery.*)

Treatment of Burns—General: If carbonic-oxide poisoning is present, artificial respiration and administration of oxygen. For shock, opium and stimulants. Local.—For burns of the first degree, powder with boracic acid. Puncture blisters, and cover the part with an antiseptic dressing. Burns of deeper degrees than the second must be made aseptic with 1 in 1,000 perchloride of mercury. Carbolic acid is absorbed readily, and must not be used. Antiseptic gauze dressings should then be used. Picric acid (20 grains to 1 ounce of water) is used as a dressing. It lessens the pain, and can be left on two or three days. The continuous bath may be used. If the burn be of any size it should be skin-grafted, as the scars of burns contract very much, and may produce deformities.—(*Aids to Surgery.*)

9. *Diagnosis of acute appendicitis:* "When the three cardinal symptoms of the disease are present—that is, sudden onset of acute abdominal *pain*, followed by *vomiting*, occurring in one previously well; unilateral *rigidity* of the right lower abdominal wall; *tenderness* over the site of the appendix—the diagnosis of appendicitis is warranted in nearly every case. . . . Failures in diagnosis, however, may often be explained by the fact that the initial symptoms were insignificant, were lost sight of, or were obscured by the injudicious use of opium." (Deaver).

In *renal colic*, the tenderness is not localized, the pain radiates to the groin and testicle, there is hematuria, and an *x*-ray picture will often show the location of the calculus.

Operation for Removal of the Appendix.—"An in-

cision is made at right angles to a line (at the junction of the outer and middle thirds) joining the umbilicus and anterior superior iliac spine, one-third being above and two-thirds below it. The cecum is found, and the anterior longitudinal band is traced down to the appendix, which usually comes off from the inner side and runs inwards and downwards. If not found there, it should be looked for in the retrocecal pouch or on the outer side of the cecum. The meso-appendix should be ligatured and cut through, a collar of peritoneum turned back, and the mucous and muscular coat ligatured near the base and cut off. The peritoneum should be stitched over the stump, and then the stump should be invaginated into the wall of the cecum by running a purse-string stitch around it."—(*Aids to Surgery.*)

10. *Causes of Intestinal Obstruction:* Strangulation, kinking, volvulus, intussusception, foreign bodies, tumors in the intestinal wall or pressure due to tumors outside the bowel, fecal accumulation, and stricture.

Acute intussusception "is most common in children. It begins suddenly with severe abdominal pain and vomiting. Blood-stained mucus is passed, perhaps with tenesmus. Collapse soon comes on, and may be fatal in twenty-four hours; otherwise death occurs in a few days from peritonitis. In most cases a 'sausage-shaped' tumor can be felt, usually along the course of the colon, but lower down, or just above the pubis. The right iliac fossa feels empty. A natural cure may follow, but rarely, from sloughing of the intussusceptum, while the peritoneal cavity is protected by adhesions uniting the entering and ensheathing layers.

"*Treatment:* The reduction of the intussusception at the earliest possible moment is the only treatment admissible, and this can only be done with certainty by operation. The abdomen should be opened over the tumor if it can be felt; if not, in the mid-line below the umbilicus. The intussusception is then reduced by squeezing out the entering portion, beginning at the lowest part. The intestine should never be pulled out, for fear of tearing it. If there is any difficulty, the wound must be enlarged and the lump brought out. If, owing to adhesions, reduction cannot be done, the intussuscepted portion must be excised through an incision in the ensheathing layer, but the outlook is bad in these cases. If the bowel is gangrenous, the condition is so bad that nothing more can be done than to bring out the coil and establish an artificial anus. If, owing to any reason, an operation is not possible, non-operative procedures must be tried. These consist of attempting to reduce the invagination by inflation with air, or better still, by fluid. A catheter is passed into the rectum, and fluid poured in from a funnel raised not more than 2 feet. A hand is placed over the tumor to feel when the lump disappears. The objections to this are that after twelve hours reduction cannot be obtained by this method; that valuable time is wasted if it fails; that you cannot tell if the last inch has been reduced (and if it has not, recurrence is certain); that it is no use in the enteric or ileocolic forms; and that the bowel may be ruptured." (*Aids to Surgery.*)

11. FISTULA IN ANO.—*Classification:* There are four varieies: (1) The *complete*, which opens into the rectum internally and on the perineum externally; (2) the *external incomplete*, or *blind external*, which opens on the perineum but not into the rectum; (3) the *internal incomplete* or *blind internal*, which opens into the rectum but not on the perineum; (4) the *horseshoe* fistula, which extends around the rectum and opens on each side. The internal opening is generally between the two sphincters, but may be above the internal sphincter and below the external sphincter. There may be several pockets or side tracts extending in different directions.

Treatment: This consists in "the conversion of the fistula into an open wound so that it may heal from the bottom. A grooved director is passed through the fistula into the rectum, and the overlying tissues severed with a bistoury. The sphincter should never be cut more than once, because of the danger of incontinence. All branching sinuses likewise should be opened, and all fibrous tissue, with undermined skin, cut away with scissors. The bleeding is then checked, and the wound packed with iodoform gauze. If the fistula is lined with mucous membrane it must be completely excised. A blind external fistula may be excised and the wound sutured. A blind internal fistula may be converted into a complete one and treated as above. The bowels are confined for the first three or four days, and the wound dressed after each defecation, being irrigated with creolin and repacked with iodoform gauze." (Stewart's *Surgery.*)

12. The *indications for enucleation of the eye* are: "(1) Injuries of the ciliary region when the eye is completely blind, or the traumatism so extensive that the form of the eyeball cannot be preserved; (2) traumatic iridocyclitis, to prevent or cure sympathetic ophthalmia; (3) severe pain in a blind eye; (4) iridocyclitis, phthisis bulbi, and glaucoma, when accompanied by severe pain or inflammatory symptoms, and when the eye is blind or is certain to become so; (5) malignant tumors, either intraocular or epiocular, if they cannot be removed with retention of the eyeball; (6) anterior staphyloma, if the eye is blind, troublesome, and disfiguring; (7) panophthalmitis, after the suppurative stage is passed; (8) foreign bodies in the eye when they cannot be removed and cause irritation, or the eye is blind." (May's *Diseases of the Eye.*)

Enucleation of the eyeball is performed as follows: "A general anesthetic is generally given. After introduction of the speculum, the conjunctiva is divided all around the cornea, as close to its border as possible, and dissected back as far as the insertions of the recti muscles. A squint hook is passed beneath the tendon of the internal rectus, and the latter is divided with the strabismus scissors close to its insertion; then the other straight muscles are cut in the same way, together with the subconjunctival connective tissue for some distance beyond the equator. The points of the scissors must always be directed toward the eyeball and the latter stripped as clean as possible to avoid any unnecessary removal of orbital tissue. Instead of commencing with a circumcorneal division of the conjunctiva, we may begin with a tenotomy of the internal rectus and then divide the conjunctiva as we pass from tendon to tendon. The hook is passed around the globe to make sure that the attachments of the muscles have been completely divided. The eyeball is then dislocated forward by pressing the speculum backward, and thus the optic nerve is put on the stretch. A pair of enucleation scissors, closed, are passed between sclera and conjunctiva, feeling for the optic nerve; they are withdrawn, slightly opened, and the nerve is divided close to the sclera. The eyeball is held between the thumb and index finger of the left hand, and the oblique muscles, and other unsevered attachments are divided. The orbit is plugged for a few minutes to control hemorrhage, and the conjunctiva is usually closed with a single suture, which is passed through its edge at intervals and tied like the string of a pouch. The eye is bandaged and the patient kept in bed for a day." (May, *Diseases of the Eye*)

THE ABANDONMENT OF THERAPEUTICS IN MEDICAL SCHOOLS DUE TO NEGLECT OF ITS CURATIVE SUBDIVISION: PHARMACO-ENDOCRINOLOGY.*

BY CHARLES E. DE M. SAJOUS, M.D., LL.D., Sc.D., F.A.C.P.,

PHILADELPHIA.

YOU will recall that at our last meeting, one of our members, Dr. Spencer L. Dawes, a trained teacher of therapeutics, delivered an address entitled "The Repudiation of Materia Medica and Therapeutics in Modern Medical Teaching," which began with Marc Antony's admonition: "Friends, Romans, Countymen, lend me your ears; I come to bury Cæsar, not to praise him." I have, unfortunately, no classic sentence to convey my meaning so tersely but I might say: "Friends and Fellow Members, I have not come to bury Therapeutics, but to revive it."

Referring you to Dr. Dawes's paper for details,[1] I will merely recall that after recognizing in glowing terms the progress made in almost every branch of medicine, he earnestly deplores the practical abandonment of the teaching of materia medica and therapeutics in our medical schools. "Those who dominate to-day," he said, "require of a graduate two very valuable requisites: they must be able to make a diagnosis and they must know pathology and be able to make an autopsy so as to confirm their diagnosis. But treat disease, cure the sick, relieve pain and suffering—nonsense! What true scientist cares for such rot!" Another fellow member, Hobart A. Hare,[2] has graphically portrayed the evil effects of this attitude of most medical colleges upon the student, the young graduate, the interne, the medical man to whom men and women must entrust their lives and those of their children.

You will agree with me that we should deem it a moral obligation as members of the American Therapeutic Society to protest against any tendency on the part of any of our schools to divert students from their aspiration to serve suffering humanity loyally and honestly as physicians worthy of the name. Yet our obligations involve also the responsibility of inquiring whether there is not some deep underlying cause for this wholesale neglect of therapeutics, and whether it might not be possible to turn the tide.

An unlocated, open seam in the hull of a great ship has sufficed to sink it; personal analysis of the question in the course of seventeen revisions of the entire medical field for an Analytic Cyclopedia has suggested that quite as dangerous a defect exists in therapeutics. To say that there is nothing in this branch of medical science, as does the therapeutic nihilist, is naught else than testimony to his lack of knowledge upon the subject provided palliation of suffering and slowing the destructive trend of disease are deemed the sole objects of medical treatment. But may we compare the *curative* efficiency of our drugs with that of surgery, for instance—or with the wonderful showing of preventive medicine in smallpox. typhoid fever, and other destroyers of humanity?

What I deem the missing factor to be reminds me of Voltaire, the great French cynic, who, by the way, was at heart a religious man. Seeing on all sides churches dedicated to various saints, St. Peter, St. Paul, St. Luke, St. Clement, etc., he concluded that he would depart from the rule by dedicating a noble edifice to the greatest of all divinities, the forgotten One, God Himself. And thus it is with present-day pharmacology; apart from six or seven specifics and vermifuges, most of which were discovered before experimental therapeutics had seen the light of day, symptomatic treatment, very useful when used intelligently, that is to say when not interfering with Nature's own curative means, is the limit of our efforts. What should be our cardinal and paramount object, however, the cure of disease, as Dr. Dawes puts it, "is not even a secondary matter; it is simply ignored." He critically refers to the multiplicity of cults in the remedial field that have sprung upon all sides. Does this not in itself prove that pharmacology has failed in its avowed aim? Would these cults prosper if therapeutics had held its own with scientific progress in other branches of medical science which have had the preservation of life in view?

College authorities overlook a feature of overwhelming importance in this connection. They are undermining the very existence of medicine as a whole. Graduates will soon begin to realize that untrained in the treatment of disease, their calling will not be compatible with the trust reposed in them by their patients and increasingly abandon the field, leaving it open to the unscrupulous of all shades and kinds.

The salvation of therapeutics will depend, it seems to me, upon the degree of curative efficiency it can be made to attain. Were the pharmacologist to concentrate his efforts upon its main purpose, *the cure of disease, by studying the influence of drugs upon our defensive functions*, he would endow his chosen field with an attribute that would stimulate endeavor on all sides instead of repelling the practitioner, as he now does, with laboratory complexities

*President's address, delivered at the twenty-first annual meeting of the American Therapeutic Society, held at Philadelphia, May 7 and 8, 1920.

in which aggressiveness against the pathogenic factor has virtually no place. As Llewellys F. Barker worded it as far back as 1900, "pharmacotherapy is almost moribund"; let *cure* be the paramount aim of pharmacology once for all and its dying embers will be revivified into a bright flame that all medical men will hail as the great white light of their avowed aim.

How can pharmacology meet the needs of so desirable an end?

Over three decades ago, while editing the Annual of the Universal Medical Sciences, I had already realized, as Bichat had said a century before, that drug therapy was "not a science fit for a methodic mind," and, inspired by the doctrine of Confucius, that "undigested knowledge leads to confusion," set to work trying to introduce some order, where chaos already reigned supreme, through the light that clinical medicine, the ductless glands, and other collateral branches might cast upon them.[3]

Two discouraging factors, however, asserted themselves from the start. Even years later, these could be illustrated, by the estimates of well-known observers. Sollmann, our most prominent experimental pharmacologist, for instance, wrote in 1908: "Pharmacology cannot be classed as an art, nor a science, it can only be classed as a confusion." The same has been said by many concerning the prevailing knowledge of endocrine functions. Thus, Prof. Halsted, of Johns Hopkins, wrote five years ago: "It must be evident to everyone that there reigns the greatest confusion on the subject of the functions of the glands of internal secretion." That such is the case anyone can readily verify to-day by glancing through the literature on experimental endocrinology. Briefly, two great confusions were available as sources of knowledge to carry out my purpose! This led me to seek for truth independently, *i.e.* irrespective of conclusions previously reached by others, with what experimental and clinical data had been published up to the dawn of the present century. The product of this labor was published as you well know in two large volumes, the first of which appeared at the beginning of 1903.

Those of our fellow members whom, for so many years, I have addressed since then upon endocrinological subjects, well know that my views, particularly those derived from the clinic, often failed to harmonize with those of psysiologists and pharmacologists. Beginning with the adrenals, I failed to find in the sick human biped, though anxious to do so, what physiologists saw in their comparatively diminutive and healthy laboratory quadrupeds. I did not find, for instance, that therapeutic doses of adrenalin or suprarenal gland inhibited the functions of the gastrointestinal canal, as physiologists would have us believe; in fact, these agents often had an opposite effect. Nor did I observe the much-talked-of inhibitory action on the pancreas, judging from the intestinal digestive processes. Even the effect on the blood-pressure failed to materialize in practice—only large doses of adrenalin or suprarenal gland or long continued dosage sometimes causing a rise—along, I might add, with effects recalling those of strychnine. Except in distinct hypoadrenia from any cause, where the pressure was low, the supposed blood-pressure raising power of adrenalin upon which the practitioner, in obedience to physiological precepts, had until recently depended two decades, proved misleading. Physiologists of the standing of Moore and Purinton, Hoskins and McClure, Young and Lehmann, and others, have themselves, in fact, proved the fallacy of this view. Indeed, as Walter Timme[4], a clinician, wrote after an extensive test in camp at Plattsburg, "If there is one thing adrenalin does *not* do it is to produce a rise of blood-pressure."

Yet, although physiologists were themselves finding erroneous the functions they had attributed to the adrenals, Swale Vincent[5] going so far as to state that evidence warranted the belief that these organs had no definite function, they were unconsciously accumulating evidence sustaining my own views—all fundamental—in their relations to therapeutics. Briefly, their labors have increasingly shown that the functions I had attributed to the adrenals in 1903 and 1907 had stood the test of time.

When I first undertook the study of the adrenals, much evidence, for instance, had been published tending to show that the process of respiration in the lungs was far from being established. This seemed to me to account for the many gaps in our knowledge of pulmonary and metabolic diseases. I had noted in the course of eight of the revisions of the medical field for my Annual of the Universal Medical Sciences. Indeed, the diffusion doctrine of respiration, so sterile as a source of help in the study of disease and therapeutics, and so costly, therefore, in human lives—and still taught, I regret to say—had been severely criticized for decades by physiologists of the first order, Paul Bert, Müller, Bohr, and others, who showed conclusively that the absorption of oxygen from the air in the pulmonary alveoli necessitated in the blood circulating through the lungs some substance capable of actually appropriating this gas. This conclusion was further sustained, as years went by, by Haldane, Lorrain Smith, and Vaughan Harley. Bohr and Henriques[6] concluded that it was presumably "a kind of internal secretion," the nature and source of which, however, remained undetermined. A comprehensive study of the question in all its phases, including a test of my conclusions in over one hundred diseases and nearly fifty drugs, enabled me to point out that the internal secretion sought was that of the adrenals. The adrenal secretion, after entering the vena cava and passing through the right heart, finally reached the pulmonary alveoli with the venous blood. Here, I held, it became a part of the hemoglobin, endowing this pigment with its power to take up oxygen from the air and thus converting it into oxyhemoglobin.

This conception has now been sustained by several experimenters. Menten and Crile[7] in 1915, and Menten[8] in 1917, found experimentally that adrenalin, which is present in the venous capillaries of the lungs, was capable of converting hemoglobin into oxyhemoglobin and of carrying on the respiratory process. I had adduced also considerable evidence, both direct and indirect, including some furnished by many physiologists as well as clinicians, that the adrenal secretion influenced general oxidation and metabolism and that it increased the intake of oxygen and the output of carbon dioxide. Recently, again, Tompkins, Sturgis, and Wearn[9] found that intramuscular injections of 8 minims of the 1-1000

solution of adrenalin caused an increase of the air intake, also of the total gaseous metabolism while augmenting the respiratory rate. It has been objected that the proportion of adrenalin secreted into the blood was too limited to carry on this function. But the adrenal principle, being an oxidizing catalytic enzyme, it is not destroyed while carrying on its functions, and *is secreted only to replenish loss* after marked fatigue or unusual excitement—a fact which explains, from my viewpoint, why Cannon observed an excessive production of adrenin in excited animals—his emotion theory. The adrenin forming part of the hemoglobin, and which has been found in the red corpuscles by Justus, is the real measure of the asset of adrenin in the blood, and not what the adrenal bodies secrete, which may be *nil* under normal conditions and excessive under excitement or stimulation.

What connection can this function, this direct connection between the adrenals and the respiratory process, both in the lungs and tissue cells, have with the cure of disease?

By the term "pharmaco-endocrinology" I mean *knowledge of the manner in which drugs influence the functional activity of the ductless glands.* If, for instance, we can with any drug enhance that of the adrenals, we are able, therefore, to increase at will not only respiratory activity, but also tissue metabolism, the very foundation of all functions. Again, many investigators, beginning with Abelous and Langlois, have also attributed, on good grounds, an antitoxic function to these organs. A. Marie, in 1912, showed that adrenalin caused active neutralization of bacterial toxins. This important defensive rôle finds its explanation in the function just described, that of sustaining as far as the oxygen supply is concerned, general metabolism. As metabolism includes among its effects stimulation of all organs and tissues which produce all defensive agents, both humoral and cellular, any drug capable of increasing the functional activity of the adrenals must enhance our resistance to disease. Have we any such drug?

As far back as 1903[10] I wrote: "Strychnine, of all agents, stands prominently as the most active suprarenal stimulant" for various reasons submitted at the time. In 1907[11] I further developed this view, citing among other data, H. C. Wood, Sr., and Cerna's observation[12] that the injection of strychnine produced an extraordinary increase in the respiratory air-movement, the increase varying from 75 to 300 per cent. Reichert, Kionka, and Mosso had also noted this phenomenon, which occurred as well in morphinized, chloralized, and curarized dogs as in normal animals. Obermeier[13] had also found that the excretion of carbon dioxide was greatly increased. Briefly, I then showed that its action corresponded, as to metabolic exchanges, temperature, blood-pressure, glycosuria, and other typical effects, with those of the adrenal secretion.

Here again, time has sustained me. In an elaborate study of the subject, Stewart and Rogoff[14] found that strychnine caused a marked increase of adrenin from the adrenals in the dog and cat, ten times the original output having been observed in some instances. The increase was not transient, but persisted during the hour and a half the experiment lasted. "Indeed," they state, "with the smaller doses the effect may go on increasing during the whole experiment." . . . "Doses of strychnine well within the therapeutic range and which cause little or no exaggeration of reflex excitability are capable of producing a considerable augmentation in the rate of output."

Need I urge that strychnine and nux vomica are our preferred tonics, as illustrated vividly by their efficiency in the asthenia following influenza? But this is not the only drug which stimulates the adrenals. If it were not for that curse of therapeutics, the drug addict, we would have in very small doses of cocaine, as well illustrated by the muscular power and resistance with which the Peruvian Indian is endowed by chewing the erythroxylon coca plant, a still more powerful "defensive tonic," if I may so term it. In digitalis and quebracho (aspidosperma) we have partial though powerful excitants of adrenal activity. In caffeine, coffee, and tea we also possess adrenal stimulants, but likewise only when used in moderation. Indeed, it is the intemperate or immoderate use of *any* stimulant that alone does the harm; even water drunk in excess has killed.

In excessive dosing lies also a misleading and most harmful feature of experimental pharmacology: the habit of giving internists as the physiological action of a drug, studied in animals, what toxic doses produced in them. The "inhibitory" fallacy of the action of therapeutic doses of adrenalin is a product of this error, the phenomenon being due to *excessive* constriction of the arterioles that supply the organs affected and arrest, therefore, of their functions. As Sollmann[15] says in this connection: there is no "good evidence for the theory of Eppinger, Falta, and Rudiger that epinephrin inhibits the internal secretion of the pancreas." This applies also to Ott's inhibitory action upon peristalsis insofar as therapeutic doses in man are concerned.

The foregoing examples show that it is quite possible to increase at will, with several drugs, the activity of the adrenals and therefore their antitoxic functions. Yet, how control the opposite condition, excessive activity of the adrenals?

We know that various disorders, sexual, muscular, and cutaneous, including hirsuties, etc., the symptom complex also of hypernephroma, are traceable to excessive adrenal activity, or hyperadrenia, or to the presence of an excess of adrenal tissue, adrenal rests, etc. This causes in some cases a pseudo-type of high blood-pressure due to excessive constriction of *all* arterioles, and the increased vascular tension behind them. Many cases of arteriosclerosis are traceable to excessive adrenal activity. How control this harmful process?

This action of the adrenal secretion, as is well known, is exerted upon the unstriated muscles of the arterioles, as demonstrated by two physiologists, Oliver and Schäfer, in 1894. Now, we have in nitrites *precise antagonists* to this function when the adrenals are overactive. Quite unaware of this action, Cushny[16] writes, for instance: "The seat of action of amyl nitrite is the unstriated muscle of the arteries and veins." Solmann also writes: "The fall of blood-pressure is due entirely to the extensive vasodilatation produced by the direct action of the nitrite on the arterioles. The vasomotor center is not inhibited." Practice proves that these statements are perfectly true. It is in the cases of per-

sistent hyperadrenia with high blood-pressure referred to above, that I have mainly observed what has rightly been termed pseudo-angina pectoris. How rapidly the nitrites and correction of dietetic errors will remove this disorder is well known. Benzyl benzoate, recently introduced by Macht, acts similarly.

We have now seen that we can actually govern with certain drugs the functions of a set of glands which influence not only the very life process itself through oxidation and metabolism, but also—and what is directly connected with our therapeutic aims—our autoprotective functions themselves.

This it not all, however. Other potent resources are at our disposal. One of these is the thyroid gland. I need hardly recall the powerful influence of this organ on metabolism—or rather on the catabolic phase of metabolism—that which causes the thyroid hormone to first break down fats, and then other soft tissues. But there is a function which physiologists and pharmacologists have always studied very imperfectly because it belongs in reality to a domain other than theirs, that of immunology. I mean the *defensive* function of the thyroid, so active at times that it destroys not only bacteria, toxins and toxic wastes, but also the tissues themselves. Among the large number of sufferers from disorders due to the thyroid apparatus observed in the clinical field—the school to which a great physiologist, Pawlow[18], referred as "an endless series of the most different and unusual combinations of physiological occurrences which never make their appearance in the *normal* course of life" —I have seen the erethitic and overactive thyroid steadily destroying body and mind, but I have also seen it yield permanently after a focus of infection, whether in the stomach, the intestines, the tonsils, etc., has been removed. Even that destroyer of adolescence, which has been sending 30,000 children to our asylums every year, dementia precox, is beginning to succumb to treatment in which the antitoxic and bactericidal functions of the thyroparathyroid apparatus were taken into account. In these cases the phosphorized fats of the cerebral cells were yielding with other fats to the catabolic influence of the thyroid hormone, secreted in excess to destroy the pathogenic agent—of intestinal origin in most cases. Have we not in all these cases evidence to the effect that poisons of various kinds may enhance thyroid activity? Why should not appropriate drugs also do it?

Again, who in the practical field does not know that the cretin and other hypothyroid subjects are highly sensitive to infections and that they succumb promptly unless the cause of their vulnerability is recognized and antagonized when they are exposed to an infection?

Referring to the paper read before this Society last year[19] in which I reviewed this whole question, I will merely recall that in 1907[20] I assimilated the defensive rôle of the thyroparathyroid apparatus to Wright's opsonins, its influence on metabolism causing it also to enhance the production of alexins in the sense given this term by Buchner, *i.e.* defensive proteins. This interpretation has also been sustained. Leopold-Levi and H. de Rothschild[21], of Paris, for instance, state: "Sajous has attributed among the functions of the thyroid body a role to the latter which he assimilates to that of opsonins and autoantitoxins. Miss Fassin, M. Stepanoff, and M. Marbé have confirmed on their side the influence of the thyroid on the blood's asset in alexins and opsonins." The first investigator did her work in the Bacteriological Institute at Liége, Belgium, the two latter at the Pasteur Institute of Paris. Lt.-Colonel McCarrison, of the Indian Medical Service[22], reviewing my labors and those of several other observers, also wrote: "While making every allowance for errors of observation, these and other findings of a like nature justify the belief that the thyroid gland contributes largely to the body's antitoxic and bactericidal functions."

Notwithstanding all the evidence available, which collectively would suffice to fill a volume, works of pharmacology make no mention of this defensive function of the thyroid; or if they do, it is merely to quote the observation of Reid Hunt, who found that while thyroid extract decreased the susceptibility of mice to acetonitril, it increased that of rats and other animals to the same poison. Now, acetonitril acting by freeing prussic acid, it is a paralyzant and cannot be expected to increase defensive activity. This applies also to various vascular depressants, which as such impair functional activity including our defensive resources.

The thyroid apparatus being undoubtedly endowed with defensive functions, how can these be brought into play by our drugs? Everyone knows that when all else fails, the iodides will often yield results. How these beneficial effects are produced has never been revealed. Cushny, for instance, says[23]: "Although the iodides have been more largely used in medicine than any of the other salts of the alkalies, their mode of action is still wrapped in obscurity." In referring to iodine, the same pharmacologist writes, however: "The administration of iodine leads to an increase in the iodine of the thyroid gland," and alluding to the symptoms of iodism and others, he adds: "Many other symptoms which have been observed under iodine treatment obviously arise from the excessive activity of the thyroid gland"—thus making it evident that it is through the "body's antitoxic and bactericidal functions" that the iodides produce their curative effects.

But we have more than the iodides. Our older members will doubtless remember that over three decades ago calomel was practically the sheet anchor as initial treatment in infections. And it undoubtedly saved as many lives as the modern highly trained physician exposes when he administers a nitrite—the household sweet spirit of niter—to offset the fever that Nature is evoking to check a disease. In 1907[24] I studied the effects of calomel and in an article containing eighty-one references, urged that in *very small* doses—never over 1/12 grain doses or less—those we used to call "tonic doses," calomel was probably our most powerful defensive agent. I then wrote, as I would now: "The functions of the pancreas, the thyroparathyroid apparatus, and the leucocytogenic organs being correspondingly activated, the quantity of autoantitoxin in the blood is augmented," all of which the more recent observations of Epstein and Pribram[25] and Krohl[26] have only served to confirm insofar as conferring immunity is concerned. This applies to all infections. In the hands of many, long ago, cases of diphtheria treated with calomel gave a mortality as low as antitoxin. Sellden[27] reported

1,400 cases treated by colleagues and himself with cyanide of mercury, the doses averaging 1/160 grain with a mortality of only 4.9 per cent. Another phase of the value of calomel is illustrated by a personal experience aboard a Cunarder returning from Naples in 1910. The ship surgeon came to me for assistance in checking an epidemic of diphtheria in the steerage which, despite the active and prompt use of antitoxin obtained from an excellent source, caused many deaths. The children, of Hungarian immigrant parentage, being found puny and ill-nourished, I advised, besides the antitoxin, calomel in doses averaging 1/12 grain every hour three times, then every two hours. The deaths ceased at once. By stimulating the defensive activity of the thyroid, the calomel caused the addition to the blood of antibodies which, added to those supplied by the antitoxin directly, promptly overcame the toxemia. Conversely, all those who have treated many cases of Graves's disease are familiar with the inhibiting influence of ergotin, arsenic, and other agents on the erethitic and overactive gland.

These examples, to which many could be added, must suffice to illustrate the resources that pharmacology offers when endocrinology is used as foundation to attain our object. The remedies used as examples being familiar ones, it would seem as if I had been treading a well-worn path. Yet, progress lies hidden behind their use as regulators of endocrine activity. As excitants of the ductless glands these well-tried agents can be made to promote the appearance, in the blood and cells, of antibodies as active in aborting disease in its incipiency as vaccines have proven efficient in preventing disease. As depressant of the same organs, other familiar drugs can be made to control exuberant activity sufficient to destroy body and mind, a morbid process typified by hyperthyroidism, and which prevails in several destroyers of mankind.

Last year, Sir Almroth E. Wright[28] wrote that the Great War had taught the surgeon that if he excised all devitalized and heavily infected tissues and brought the walls of the wound together, the protective mechanism of the body could, without antiseptics, deal successfully with every kind of infection. What I would submit in the present connection is that we have in the ductless glands intermediaries through which our drugs can, as do vaccines, so enhance the efficiency of that protective mechanism as to arrest disease, before it has had time to compromise life. Organotherapy has enabled us fully to realize the influence of the endocrines upon morbid processes, and pharmacoendocrine therapy will be the second step which will reveal their true importance as weapons in our warfare against disease.

Viewed in this light, pharmacology will assume its true rôle; it must, indeed, eventually become the queen bee of the hive, which all branches of medical science will feed and raise to the highest degree of efficiency. When all this will have been adequately developed and duly apprehended, there will be no more question of abandoning therapeutics in our medical schools, for after all, it is our mission as physicians to cure disease, and to abandon sufferers to its destructive inroads is no less a crime than it is for the soldier to desert the flag in the presence of the enemy.

TISSUE ACIDOSIS VS. BLOOD ACIDOSIS.*

BY WILLIAM H. MERCUR, M.D.,

PITTSBURGH, PA.

THIS brief paper is written for therapeutic purposes only. Certain facts in literature concerning the subject of acidosis are only briefly mentioned and summarized in order to make clear certain definite therapeutic indications. The fundamental theories of acidosis have so often been presented in recent writings, principally by James I. Whitney, L. G. Rowntree, Andrew W. Sellards, and Albion W. Hewlett, that it is hardly necessary to cover the ground anew, further than to state that my conception of what acidosis is, either a blood acidosis or a tissue acidosis, is comprised in two very comprehensive definitions, one by A. W. Sellards and one by A. W. Hewlett. Definition by Dr. Sellards:—"An acidosis is a diminution, from any cause, in the reserve supply of fixed bases in the blood or other tissues of the body, the physicochemical reaction of the blood remaining unchanged except in very extreme conditions." Definition of Dr. A. W. Hewlett's: "Acidosis is due to the formation or retention in the body of an excess of non-volatile acid substances. As a result of the process, the blood carbonates are in part decomposed and their quantity lessened."

These two definitions, if accepted, point the way

*Read at the annual meeting of the American Therapeutic Society, held in Philadelphia, May 8, 1920.

very clearly to rational methods both of diagnosis and therapeutics. Dr. Sellards, in his recent valuable little book on "The Principles of Acidosis and Clinical Methods for Its Study," states that it is only necessary to classify acidosis according to its etiology and that it is not necessary to subdivide the principles upon which the theory of acidosis rests.

Dr. Whitney, whose most valuable studies on acidosis are well known, sums up, as follows, the etiological factors under four general groups:

1. *Overproduction of acid due to deficient oxygen,* such as severe exercise, mountain sickness, acute anemia, gas poisoning and asphyxia, decompensated heart lesions.

2. Conditions where a primary lack of oxygen leads to a compensatory raising of the threshold for acid, such as acidosis of high altitudes, acidosis of pregnancy.

3. Metabolic conditions in which abnormal acids are produced in large amounts such as in diabetes mellitus, starvation, postoperative toxemias, diarrheas and cyclic vomiting in children.

4. Kidney inefficiency, such as in chronic nephritis, pus kidney, etc.

If, therefore, these various groups of possible etiological factors are borne in mind, the possibility of an early correct diagnosis will be much facilitated. The author has found, in making a comprehensive study of the subject of acidosis, that the nomenclature adopted in discussing acidosis in current literature is most confusing. Whenever it is necessary to refer to current medical literature, references are secured *first,* under certain classifications; and *second,* under certain nomenclatures or nosological headings.

As a rule, it is a comparatively easy matter to look up the literature concerning a special disease or condition under some of the well recognized and accepted classifications of diseases, especially those which deal with disease conditions strictly from an anatomical or etiological standpoint. The matter, however, becomes much more complicated and confusing when we approach our subject from the standpoint of our present nomenclature. This is especially confusing when we attempt to deal with a broad general subject, such as acidosis, which has so many different phases and can be approached from so many angles. I recall, very vividly, attending a symposium on Acidosis in May, 1916, before the Association of American Physicians in Washington. Before the discussion began, I thought I had a few definite, more or less fixed, ideas on the subject, but before the symposium was over, I was so confused that I did not know whether I was standing on my head or my heels, and the little that I thought I knew had vanished. Dr. Yandell Henderson, professor of physiology at the University of Yale, partially saved the situation for me by pointing out, in closing the discussion, that the matter was really not quite so confusing as it seemed, because everyone was really talking about the same subject, but was approaching it from a different angle, and that even when their views were the same, the nomenclature, which they used to express their views was different, although all really meant one thing. Assuming that there were ten possible different expressions, any one of which could indicate the same thing, and that ten different men each selected a different one of these ten, one can easily imagine the confusion that arose in that discussion.

It might be well to emphasize again the fact that there are only *two* well recognized methods to play the scientific game, and if those of the medical profession, whose aim it is to assist the profession, either by writing or by teaching, would strictly adhere to the rules which govern these two methods, much time would be saved, and, incidentally, much less would be written. The first method is to collect your facts, and then try to adjust your problem to these facts; and, second, to assume a plausible hypothesis as a possible explanation for certain problems and then try to prove your hypothesis from facts. Both are valuable and necessary under certain conditions, but neither should be confused with the other. There is nothing so confusing as to listen to a man, or to read what he writes, when he is constantly confusing his facts with his hypotheses. In the present communication, the author will endeavor to confine himself strictly to the first method and only in one instance will make use of the second method.

1. *Tissue Acidosis vs. Blood Acidosis,* or 2, *Hypoalkalinity of Tissue and Blood* (*Sellards*). My title in the first place is a misnomer and a most unfortunate use of the term; as, strictly speaking, neither the tissues of the body nor the blood can be said ever to be acid in the usual sense of the word. Hence, the title adopted by the author, suggested by Dr. Sellards, of hypoalkalinity, is much to be preferred from an etiological standpoint. In this connection, I would like, briefly, to call your attention to certain comparatively recent facts which have quite a practical bearing on the subject we are discussing. First, the recent epidemic of acute anterior poliomyelitis, commonly, but most erroneously, called infantile paralysis, for the facts brought out in the study of this condition proved conclusively that only about 10 per cent. of the cases affected have paralysis, and that individuals reacted, in this disease, strictly according to their individual powers of immunity; so that some of those exposed established their immunity in less than twenty-four hours, with the production of but few symptoms, while others would go on to the state of paralysis, or die before that stage was reached. In like manner, the late war taught us a similar lesson in regard to epidemic cerebrospinal meningitis. Dr. Herrick, of New York, in a masterly review of this subject, in which he reviewed hundreds of cases seen by him in an army camp, demonstrated the fact that the same was true in this disease and that the meningeal syndrome was but a late manifestation of its symptomatology.

The author would like to draw a similar comparison in discussing the subject of acidosis and to emphasize the fact that an acidosis may be either very mild or even most transitory in character, at one extreme of its origin or development, and very severe and dangerous at the other; and also, that in between these two extremes, a large number of intermediate varieties can be found. He is convinced that heretofore our attention has been so fixed, by various authors, upon the importance and the dangers of the more or less terminal forms of acidosis, that we have neglected, not only to recognize but especially to treat the very large number of mild

cases of acidosis. To recapitulate, we have been taught to diagnose acidosis clinically only when it has reached a far advanced stage of its normal development, exactly as formerly we regarded, clinically, acute epidemic anterior poliomyelitis and epidemic cerebrospinal meningitis. These remarks will be limited chiefly to the subject of the early diagnosis and treatment of the very mild cases of acidosis with which the author has had considerable personal experience, and he would like to point out in this connection the desirability of someone making a careful study of the corresponding mild cases of alkalosis.

What, then, are the well-established facts so far as they have been observed and substantiated in regard to acidosis or hypoalkalinity?

Several years ago, a friend of mine, who had given a great deal of attention to the chemistry of the blood and especially the laboratory methods of studying it, expressed to me, briefly, his views by making use of the following diagram. This diagram has been so valuable to me in following up advances in this subject, that I am going to reproduce it here for my guidance, in making clear to you, the therapeutic points which I wish to bring out and to illustrate.

20 per cent. "Buffer Salts." 80 per cent.
A.——————————————————B.
Acid Radicles. Alkaline Bases.

Imagine all the blood in the body to be represented by a straight line A to B. The blood is a fluid which from a chemical standpoint is composed, approximately, of 80 per cent of alkaline bases and 20 per cent of acid radicles. This proportion, which usually is remarkably constant, is held in balance by what Rowntree has recently most beautifully described as "the buffer salts of the blood." When the blood is thus delicately in balance, it is possible to eat almost any quantity or variety of food and the end results of all food metabolism, be it either that of an alkaline base or that of an acid radicle, will be the same, for the "buffer" (when in good working order) promptly takes up an excess on either side and thus the delicate balance is not materially changed. When, however, anything goes wrong with the "buffer" or fly-wheel, then trouble begins and we have either an acidosis on the one hand or an alkalosis on the other; either of which may be accompanied by most serious conditions, especially if either is prolonged or far advanced.

Let us now continue the study of our diagram and analyze, a little more in detail, what are the facts about our 20 per cent of acid radicles. Let the upright line represent, diagrammatically, the acid content of the blood. Of this, 15 per cent of its bulk (approximately) is made up of volatile acids and the balance of (approximately) 85 per cent is non-volatile acids. The 15 per cent of volatile acids are thrown off, principally, through the lungs as CO_2 gas. The 85 per cent of the non-volatile acids are excreted principally through the urine and very slightly through the feces.

15%	Volatile Acids CO_2	Lungs.
85%	Non-Volatile Acids	Urine and Feces.

This diagram makes it quite evident that, if the non-volatile acids, as a result of deficient elimination, accumulate in the blood, the volatile acids will be thereby compressed and the amount of CO_2 thrown off through the lungs will have to be increased and thus the power to hold the breath will be more or less diminished. This is the rational explanation of the clinical value of the breath holding test of Dr. Henderson.[1]

Dr. Henderson's directions are as follows—"(1) Sit quiet for five minutes. (2) Draw a full, deep, but not too deep, breath. (3) Hold it with mouth closed and nostrils compressed with fingers. (4) Note time. (Usual normal period which breath can be held is 45 seconds. Between 30 and 40 seconds indicates a mild acidosis; between 20 and 30 seconds indicates a high degree of acidosis."

Dr. Whitney, of San Francisco, in two recent articles,[2] makes a very practical clinical suggestion which the above diagram beautifully illustrates; that it is not only necessary to give alkalies to neutralize an acidosis but that it is equally necessary, owing to the extremely loose chemical association of some alkalies with acids, to combine the alkali with either a diuretic or laxative. This latter observation is so evident and so convincing that it is surprising that no one had pointed it out before. It has been the personal experience of the author to have had the most brilliant therapeutic success when giving alkalies when the symptoms pointed distinctly to an acidosis, and also to have as great a failure when a few days later he gave alkalies under apparently similar conditions. I am free to admit that I formerly omitted giving any more alkalies in these cases; as I concluded that my patient had some idiosyncracy to that particular alkali which I was using, and the idea never occurred to me that my failure was due to the fact that I had not combined my alkali, as Whitney suggests, with either a diuretic or a laxative to carry it off.

Before proceeding to the main point of my paper, the treatment of tissue acidosis *vs.* blood acidosis, let me refer in passing to a most important series of experiments that have recently been published in the *British Medical Journal* by Dr. Hamburger of Gronningen, Holland, in regard to the action of mild degrees of acidosis on the leucocytes, especially in regard to their phagocytic action. His experiments show that normal white blood cells in a blood with a proper balance between alkali and acid bodies can normally take up 50 per cent of their bulk of bacteria, but that the instant this balance is lost, even to a slight degree, they can absorb only 25 per cent of phagocytes. In other words, the great practical bearing of his researches was to show that in any infection, associated with an acidosis, alkalies are always indicated in order to raise the powers of our leucocytes (of our little white soldiers) to resist disease from 25 to 50 or 100 per cent.

Returning to our principal subject. What clinical signs have we at our disposal to distinguish between a mild blood acidosis and a mild tissue acidosis? Which begins first? Does the tissue acidosis affect the blood or does the blood acidosis affect the tissues? Frankly, I do not know. Both Fisher and Henderson assume that the process begins in the cells and through the cells ultimately reaches the

blood. Others take the opposite view. Clinically, it would seem as though the acidosis should reach the cells through the blood.

We now have many simple, reliable, and easily carried out methods, by means of which we can determine whether our "buffer" has lost its power, and I am inferring, although I have no scientific facts to prove, or proofs to sustain, my contention, that if the buffer is not acting, and this continues for any length of time, the blood which is constantly bathing all the tissues, will in time give them more or less of an acid imprint, which remains for an indefinite period. In treating these cases, therapeutically, I first try to determine this point and in all cases in which a tissue acidosis is assumed, I tell the patient that the treatment will be a long drawn out one, and will involve a more or less constant use of alkalies, probably for many months.

Early diagnosis of Blood and Tissue Acidosis.—The two simplest and most easily carried out tests are (1) The breath-holding test of Henderson. (2) Litmus paper test: (*a*) Saliva. Normal is alkaline before meals, acid after. (*b*) Urine. Normal acid. (*c*) Stool. Normal alkaline.

Both of the above tests are reliable and easily carried out and, when positive, indicate when treatment should be begun.

Some of the simplest and most easily carried out chemical and laboratory tests are

1. Reaction of blood serum to phthalein.

2. Ingestion of sodium bicarbonate on reaction of urine (Sellard's test). Five gm (5) sodii bicarbonate is given by mouth; the urine should be neutral or alkaline in three hours if normal.

3. Dr. W. J. Bruce[3] gives the following simple test for determining the reaction of the stool. Prepare first a 1 per cent. solution of alizarin. (*a*) Place then on a slide two drops of this solution 1½ inches apart; one of these drops in the control. (*b*) Use a glass rod which has been dipped or thrust into feces either liquid or solid. Mix thoroughly with one of the drops. Alkaline reaction = reddish violet to violet. Acid reaction = light yellow. Neutral = no change.

4. Another very simple and easily applied test has recently been suggested by Dr. C. Mitchell[4] which he calls the iodine color test for determining whether acidosis exists; for he points out that the acidity of the urine alone is not to be depended upon as a sure diagnostic sign of acidosis nor is the presence of acetone bodies, nor a chemical reaction to ferric chloride, as these reactions may be caused by other non-specific factors. A busy practitioner requires most of all a simple trustworthy urine test which may be carried out without special apparatus and chemicals difficult to obtain. The technique of the test he suggests is as follows:

Add to 145 c.c. water 3 c.c. Lugol's solution, and 2 c.c. Sat. solution of picric acid. Mix thoroughly. The result is a clear bright reddish liquid. Pour this liquid into a white dish and heat gently (do not boil) until fumes are abundantly given off. To this hot liquid add urine as follows: (1) Normal acid urine up to 15 c.c. does not change color of above hot fluid. (2) Urine, although acid, but which indicates an acidosis in amounts from 2 c.c. to 10 c.c., will change the above liquid from a bright reddish color to a bright yellow.

Among other early symptoms which may be mentioned are the following: Slight mental irritability; a tendency to hives and eczema; a tendency to a low-grade conjunctivitis associated with subconjunctival hemorrhages and a collection of matter in the inner corners of the eyes. Presence of a heavy or disagreeable breath is also a very important and reliable early symptom.

Treatment.—To be correct and efficient, treatment must depend not only on the etiology of acidosis but also on the fact whether it is a mild or severe case. A mild acidosis treated with too much alkali can easily be converted into an alkalosis.

1. If the etiology indicates that the "buffer salts" are defective from any cause, give alkalies such as the carbonates and citrates of sodium potassium, and calcium.

Dr. T. C. Ely[5] quotes A. Taylor as saying: "As the acids circulate in the system, they abstract from the tissues sodium, potassium, and calcium and disturb the equilibrium of the basis elements in the tissues. Obviously the correct therapeutic measure is not to administer only one type, but a mixture of sodium, potassium, and calcium in order to restore the equilibrium."

2. In acidosis of nervous origin, which is quite often associated with disturbances in the action of the buffer salts, the old prescription known as pil. sumbul comp., which contains Hyoscyamus, ½ grain; Camphor, 1 grain; Powdered Valerian, 1 grain; Ext. Sumbul, ½ grain, is often of surprising value. It can be given as often as once every half hour for three or four doses.

3. In cases where an endocrine loss of balance is suspected as a cause of acidosis, the use of chromium sulphate in four grain doses usually works surprisingly well. The author has given this remedy empirically for a great many years. He has no explanation to offer why it should have such a good effect other than hazarding the hypothesis that chromium may in some chemical way influence some of the endocrine glands.

4. Treatment of acidosis due to certain diseases, as diabetes mellitus, starvation, after surgical operations, cyclic vomiting, diarrhea, infectious diseases of childhood, nephritis and other diseases of kidney should vary with the disease in question.

5. It should not be lost sight of that acidosis may be due to carbohydrate excess. Both Dr. W. J. Stone[6] and Dr. W. Tileston[7] have commented on this matter.

6. Various gastrointestinal disturbances are often associated with a mild or a severe acidosis.

7. The influence of diet upon treatment, in acidosis, does not, as yet, seem to have much clinical value.

8. Transfusion from an alkalinized donor as suggested by the late Dr. Edward Lindeman.[8]

9. As a rule, give small doses at short intervals, rather than large doses at long intervals.

In conclusion, the following explanation might prove of interest of why less meat is a good treatment for acidosis. During protein digestion, the sulphur and phosphorus are oxidized to sulphuric acid and phosphoric acid. These would acidify the blood at once were it not for the presence in the blood of salts of sodium, potassium, calcium, and magnesium. When these fixed alkalies are insuffi-

cient to neutralize the acids produced, the organism makes use of a mechanism for neutralizing the excess as follows: Amino acids passing through the liver and muscles are de-amidized. That is, the amino group (N H) is broken off and changed to

$$\left(\overset{+}{H}\right) = K \times \frac{H_2CO_3}{NaHCO_3}$$

Diagram 1.

ammonia. Further, this ammonia together with water and CO_2 is converted into urea and this is execreted by way of the kidney. If, however, the blood stream brings to the liver unneutralized sulphuric acid and phosphoric acid molecules, owing to the lack of fixed alkali, then the ammonia mentioned above neutralizes the acids and is execreted as ammonia salts. Thus, the more acids produced in the organism, the more ammonia salts and the less urea are found in the urine, and vice versa.

Why Acidosis Can Be Successfully Treated with Acids.—In the *American Journal of the Medical Sciences*, January, 1917, Dr. J. Harold Austin gives the following information: The normal reaction is maintained by three methods: (1) Presence in blood of (*a*) sodium bicarbonate and other salts;

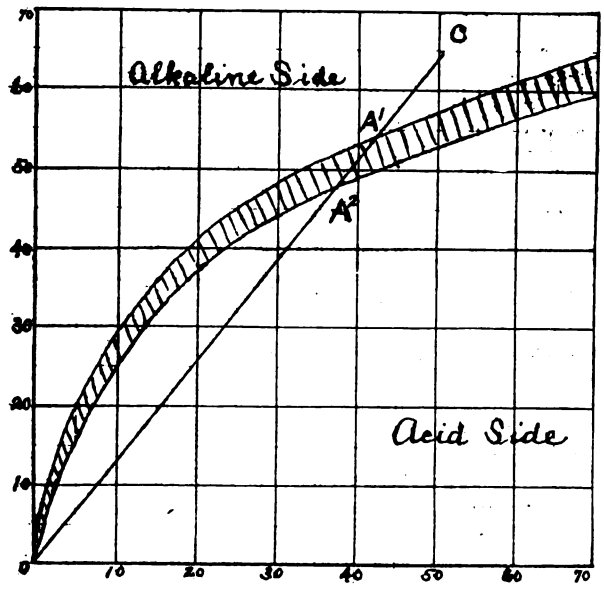

Diagram 2.—The normal CO_2 dissociation curves of normal human blood, as we have found them, are all within the shaded areas. The figures to the left indicate the CO_2 content in volume per cent., those below mark the CO_2 tension in mm. of mercury.

(*b*) two weak acids, CO_2 and phosphoric acid. (2) Rapid elimination of weak phosphoric acid through the kidneys; (3) Rapid elimination of weak carbonic acid through the lungs. When an acid is added to the blood, such as strong HCl, it combines with the sodium salts and liberates CO_2 and phosphoric acid.

Sodii phosp. + HCl = NaCl + phos. acid.
Sodii carb. + HCl = NaCl + CO_2.

Thus, for every unit of strong acid introduced into the blood, there is liberated a unit of weak acid which possesses much less power of altering the reaction of the blood. The only danger is too much strong acid.

At the meeting of the Association of American Physicians held in Atlantic City on May 5, 1920, Dr. J. H. Means, in a paper in which he discussed the acid base equilibrium in disease, gave the two following diagrams, which expressed very clearly the points he was demonstrating. Diagram 1 is one devised and published a number of years ago by Lawrence J. Henderson. And diagram 2—the CO_2 diagram—is a method of presenting acid-base equilibrium factors in graphic form which was worked out by Haggard and Y. Henderson and was published by them in 1918 in the *Journal of Biological Chemistry*.

In discussing Diagram 1, Dr. Means pointed out that much trouble arose from the fact that the denominator in this diagram was not clearly separated in one's thought from the numerator. Hence much unnecessary confusion was constantly arising. He then gave Diagram 2. In this the upper line of the curve indicates the H ion content, and the lower line of the same curve the CO_2 tension of the arterial blood. When both are normal they cross the line OC at points A^1 and A^2 respectively. Any marked changes in suspected normal cases would be indicated by a deviation either to the right or to the left of line OC.

THE THERAPEUTICS OF DECREASING BODY ALKALINITY.*

By WILLIAM H. PORTER, M.D.,

NEW YORK.

PROFESSOR EMERITUS OF PATHOLOGY AND GENERAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

For centuries, practically speaking, the profession and the lay world have been talking about body acidity or increasing acidity of the human economy, —a state of the system that can never be while life lasts. If such a condition could be produced, we would have a corpse to work upon, not a living patient. What we really have to deal with is a decreasing alkalinity of the system, not a rising acidity. There is no acid condition of the animal economy to rise. Professor John C. Dalton states this beautifully when he says: "This alkaline reaction is essential to a large number of vital processes taking place in the interior, and is present, without exception, in all the animal fluids which are contained in the circulatory system or in the closed cavities of the body. An acid reaction, on the other hand, is found only in a few of the organic fluids

*Read at the twenty-first annual meeting of the American Therapeutic Society, held in Philadelphia May 7, 1920.

which are employed in the process of digestion or are discharged externally."

To understand intelligently the therapeutics of decreasing alkalinity, we must know, first, how nature produces and maintains this alkaline state of the system; second, we must know the cause of decreasing alkalinity. With these two facts in hand we can scientifically elucidate its therapeutics.

In the oxidation reduction of the protein molecule, we have an atom of sulphur split off and eliminated from the molecule. This is done at two points. *First*, by the oxidation reduction processes which take place in some of the epithelial cells that enter into the construction of the mucous membrane of the stomach. This results in the production of a molecule of sulphuric acid which, as soon as it drops from the free surface of the cell, comes in contact with a molecule of sodium chloride, followed by the formation of a molecule of hydrochloric acid and one of sodium sulphate,—as illustrated by the following equation: $C_{72}H_{112}N_{18}O_{22}S + H_2O + 4(O) = C_{72}H_{110}N_{18}O_{22} + H_2O + H_2SO_4$. Immediately upon the formation of this free sulphuric acid molecule it attacks one of sodium chloride, with the formation of hydrochloric acid and one of sodium sulphate, illustrated by the following equation: $H_2SO_4 + 2(NaCl) = 2(HCl) + 2(NaSo_4)$. After the hydrochloric acid has served its purpose in the digestive act, it in turn attacks the trisodic phosphate, restoring the sodium chloride lost in making the hydrochloric acid and sodium sulphate, with the formation of the disodic monohydrogen phosphate, which salt is the true physiological alkalinizer of the human economy:—Illustrated by the following equation: $2(HCl) + 2(Na_3PO_4) = 2(NaCl) + 2(Na_2HPO_4)$.

The chemical mutation, as here expressed, gives an exact explanation for the production of hydrochloric acid, along scientific lines. It further proves conclusively why the elimination of the inorganic sulphates is always greater than the intake. It shows also that nature produces for herself daily a slight amount of laxative agent in the form of "Glauber's salts" thus formed. It explains at the same time how some of the chloride of sodium is destroyed and again restored to the system each and every day, keeping the intake and the output always equal.

It proves pretty conclusively that we cannot have a perfect metabolism without this salt, and that placing a patient on a salt-free diet is not based on sound physiological chemistry.

These mutations demonstrate also how the animal economy acquires its daily supply of disodic-monohydrogen phosphate, which salt is not found in this form in the food-stuffs. Without this particular salt a perfect metabolism cannot be maintained.

With these facts before us, we are in a position to study the problem of decreasing alkalinity of the system, to discover how it is brought about, what happens when it does occur, and how best to cope successfully with this abnormal state.

There are two etiological factors to be considered. *First*, the use of foods deficient in the trisodic phosphate and other mineral salts. This deficiency in mineral salts is due, largely, to the common method of cooking vegetables denuded of their protective skins. The water in which they are cooked is thrown away, and with it the mineral salts, since this fluid contains the larger part of the mineral substances in our foods—salts without which there can be no perfect metabolism. Therefore, the liquor in which all vegetables are cooked should be saved and served with the vegetables if the much-needed supply of these essential mineral substances is to be continuously supplied. By eating vegetables in their raw state, as some have advocated, all the mineral salts are taken into the system; hence the wonderful cures that have been secured by the use of vegetables in their raw state.

The *second* etiological factor is the arrest of or diminished oxidation of the protein substance in the cells of the gastric mucous membrane, as already described. This results in a deficient production of sulphuric acid, hence less hydrochloric acid and sodium sulphate. This furnishes less hydrochloric acid to transform the trisodic phosphate into the disodic-mono-hydrogen-phosphate. If there is also a deficient amount of trisodic-phosphate—as there is of hydrochloric acid—the dealkalinization of the animal economy takes place with very great rapidity. So much so, that nature attempts to overcome the difficulty by pulling the fixed alkalies from their stable position in the teeth, bones, and various structures of the body. Failing to overcome or arrest the dealkalinization, a very positively decreased alkalinity is developed. When this stage is reached, it is absolutely impossible to have anything like perfect assimilation. If allowed to continue, it brings about the state of the system called acidosis, which, to be axact, is an intensely rapid dealkalinization of the whole economy until life can no longer be maintained and death speedily ensues.

When for any reason we have an unusually large percentage of protein material oxidized in these gastric cells, it produces the condition known as hyperchlorhydria. This can be brought about in one of two ways: by the ingestion and utilization of an unusually large quantity of protein material and its oxidation in these gastric cells. This overtaxes the oxygenating capacity of the system and is, in itself, another factor in disturbing metabolism. Or it may occur as the result of vicarious oxidation of the protein material in these gastric cells; that is, by all the sulphur atoms being split off in the gastric cells, leaving no sulphur for the liver to produce its daily production of taurocholic acid—still another factor in the production of disturbed metabolism. These two conditions must be differentiated to enable us to apply our therapeutic measures with scientific accuracy. If there is in connection with the hyperchlorhydria an abundance of trisodic phosphate in the food, there will be produced an unusually large amount of disodium-monohydrogen-phosphate. This will cause an excessive alkalinity of the body fluids and structures—a state of the system which, if carried too far, will be detrimental to a perfect metabolism and assimilation. Nature, however, speedily eliminates the excess of this alkaline salt, but in so doing the urine becomes unduly alkaline, which is still another source of irritation and acts as a deterrent factor.

From the foregoing, it is readily apparent that a defective metabolism may be caused by directly opposite conditions—by a decreased or by an increased alkalinity of the body fluids and structures.

In both instances, however, the animal economy remains alkaline and always must, so long as life lasts. The treatment in the two instances must be somewhat different. As there is more apt to be a deficiency of trisodium phosphate than an excess, a mineral salts. For instancee, in the rachitic child, as Professor Jacobi used to say in his clinic, there is plenty of calcium but it cannot be fixed in position. Giving more does no good. How can it, when there is a constant dealkalinization associated with

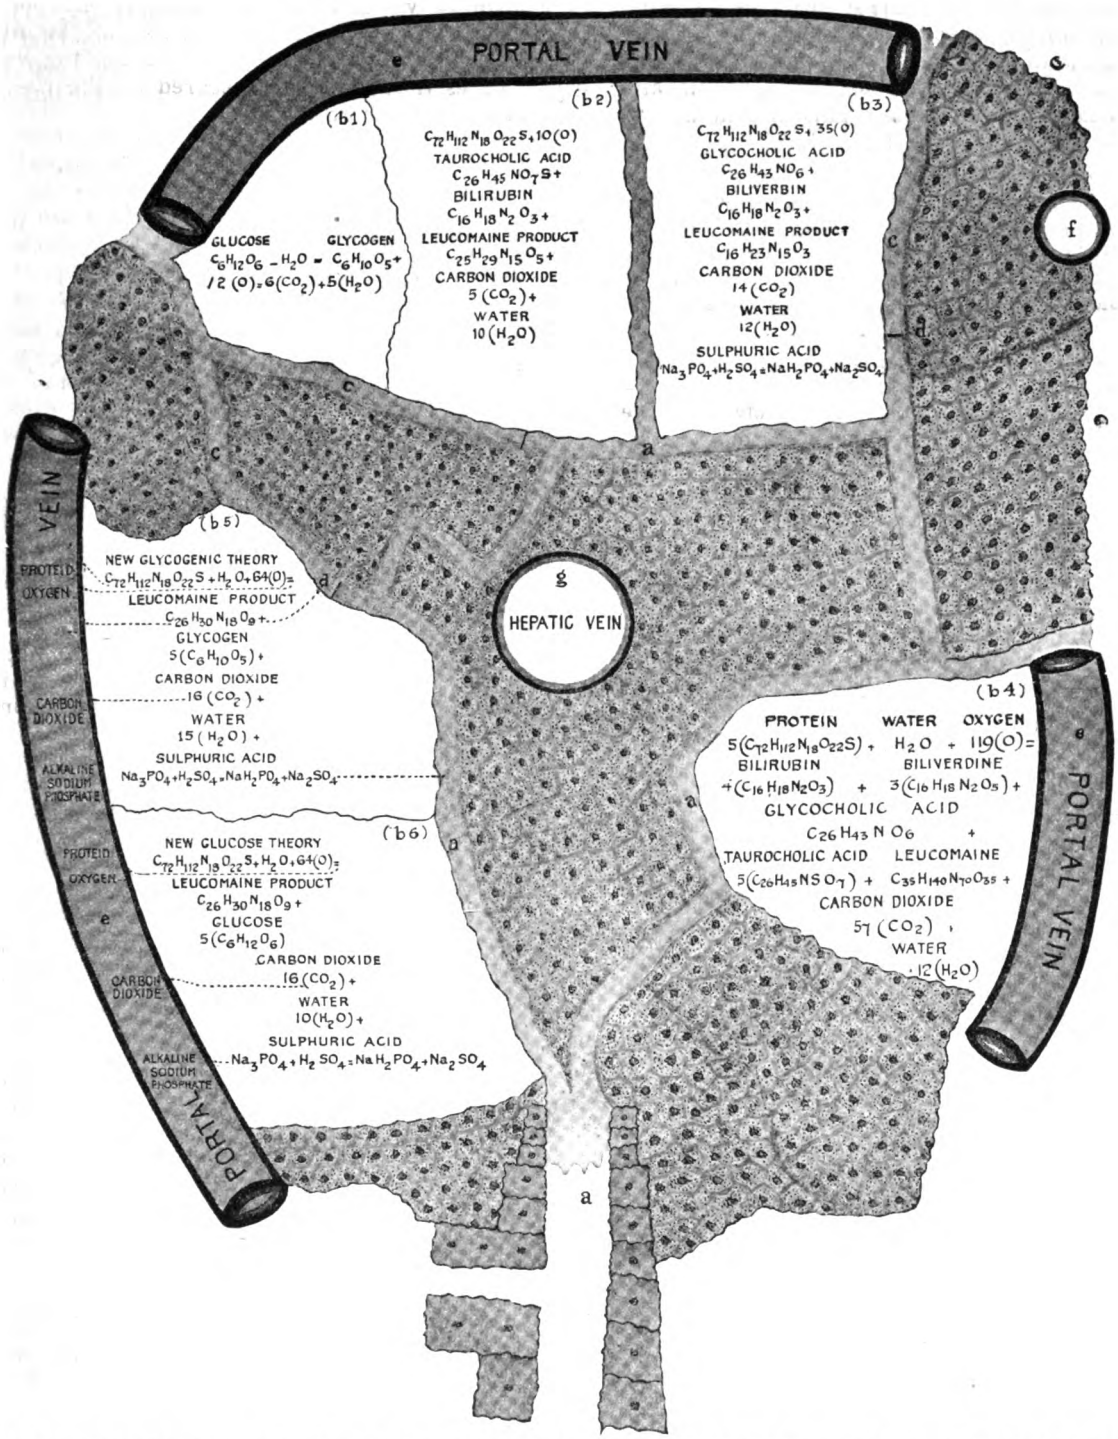

FIG. 1.—Schematic drawing of normal liver, highly magnified. *a*. Lumen of bile ducts and radicals; b^1 to b^6, hepatic cells very highly magnified, illustrating chemical transmutations within them; *c*, lumen of lymphatic channels; d, basement substance between bile radicals and lymphatic spaces; *c*, blood vessels of the portal system; *f*, hepatic artery; g, hepatic vein. (From the Reference Hand Book of the Medical Sciences, Vol. VI.)

superalkaline state is not often met with in actual practice.

Under these circumstances assimilation remains impaired, even though the quantity and composition of the food are good, aside from the defects in a pulling down of the fixed alkalies from the structures of the body continually taking place in the system?

The *second* point in the body at which nature eliminates the sulphur atom is in the hepatic cells.

Here the remaining sulphur atom in the protein material not oxidized in the gastric epithelia is reduced by a process of oxidation reduction, with the formation of taurocholic acid, biliverdine, a leucomaine product, carbon dioxide, and water:—Thus, $C_{73}H_{118}N_{18}O_{22}S + H_2O + 10(O) = C_{26}H_{45}NO_7S + C_{25}H_{29}N_{15}O_5 + 5(CO_2) + 10(H_2O)$. See Fig. 1-1b.

When this condition is developed, the normal balance between the stomach and liver elimination of sulphur is disarranged. This adds another upsetting factor to the animal economy in connection with this problem of dealkalinization of the system. The amount and quality of bile are changed. This results in less bile reaching the intestinal canal than is normally the case. This still further impairs the digestive function, and the whole metabolic process is further disturbed.

From the foregoing, we find that dealkalinization of the animal economy is no single and simple problem, but one that is quite complex and intricate from start to finish. It is one, however, that must be thoroughly understood if we are to present our therapeutic remedies with scientific accuracy. The administration of any single chemical substance, such as bicarbonate of soda, just because it is an alkaline substance and can change an acid to an alkaline reaction, does not fully meet the indications, since it does not overcome all the disturbed chemical activities and it does not furnish the physiological alkalinizer. A study of the chemical mutations, here outlined, indicates that nature, working normally, produces a special form of alkali for this particular alkalinizing process. It is the disodium-monohydrogen-phosphate—$Na_2H(PO_4)$. This salt is the physiological alkalinizer of the animal economy. It is the special salt that enables nature to hold the other mineral substances in fixed relation to the teeth, the bones and the various structures of the body. This is especially true in relation to the calcium salts. Another thing to be noted in this connection is the mode of its production, which is by a somewhat slow yet progressive manner, as a part of the digestive act, so that this disodium-monohydrogen-phosphate gradually and continuously enters the blood stream, reaching its acme between the middle and latter part of the digestive act.

It has been further established that the disodium-monohydrogen-phosphate salt is necessary and the normal method for transforming the uric acid molecule into a urate as it escapes from the renal cell into the lumen of the uriniferous tubule. At the same time that the urate is formed, a monosodium-dihydrogen-phosphate is produced. This monosodic-dihydrogen salt is the normal and true acidifier of the urine. The following equation shows how the urate and monosodic-dihydrogen molecule is formed: $C_5H_4N_4O_3 + Na_2H(PO_4) = C_5H_3N_4O_3Na_2 + NaH_2(PO_4)$. (See Fig. 2). The acidity of the urine, like the alkalinity of the system, rises and falls but the urine is always acid in reaction when the metabolic processes are normally effected.

Unless this body alkalinity is uniformly maintained it is impossible to have a perfect metabolism. For this reason alone, the necessity for reestablishing and maintaining this perfect alkaline condition is the first and most essential thing to be accomplished in the therapeutic management of imperfect metabolism and malassimilation.

By the administration of some form of abnormal alkalies, it has been my good fortune in the past to obtain some very remarkable results in the management of this class of cases. Since realizing fully the importance of using the physiological salt in preference to any other form of alkali, my results have been just so much more satisfactory. This one example alone demonstrates conclusively that in our therapeutic endeavors the nearer we keep to nature's methods in the selection of remedial agents

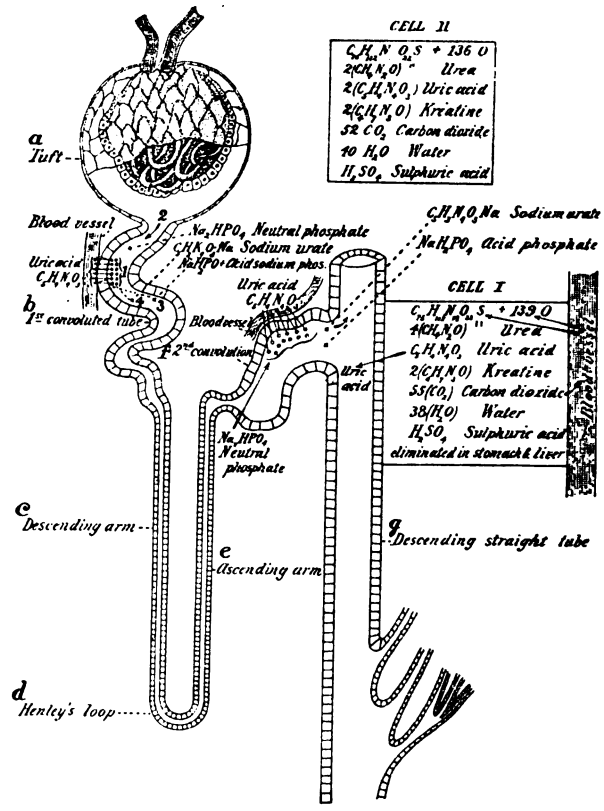

FIG. 2.—Schematic drawing showing single uriniferous tubule from Malpighian tuft to papilla or its outlet. (*a*) Malpighian tuft and blood vessels. (*b*) First convolution. (*c*) Descending arm of loop. (*d*) Henley's loop. (*e*) Ascending arm of loop. (*f*) Second convolution. (*g*) Straight or collecting tube. 1. Uric acid molecule dropping into lumen of tube. 2. Neutral phosphate of soda molecule as it unties with the uric acid to form. 3. The acid phosphate of soda; and 4. The urate of soda formed by this chemical mutation. Cell I. Magnified single renal cell, with lumen of the tube on one side and the blood vessel on the opposite side, illustrating normal oxidation of proteid molecule within the protoplasm of the cell. The proteid and oxygen coming from the blood into the cell, where it breaks up into its reduction products. The uric acid dropping into the lumen of the tube, while the carbon dioxide flows back into the blood. All the other reduction products dropping into the tube as does the uric acid. The sulphur being eliminated as a sulphate. Cell II. Magnified cell illustrating abnormal or suboxidation in the renal cell. Urea diminished one half while the uric acid is overproduced fifty per cent. In both the normal and abnormal oxidation the sulphur is found in the urine as a sulphate. The sulphuric acid molecule represented by the formula H_2SO_4 in Cell II., when it reaches the urine, is in the form of a sulphate, Na_2SO_4 or "Glauber's" salt. This salt being produced in connection with the oxidation reduction of the protein elements, in some of the gastric epithelia, in the process of producing sulphuric and hydrochloric acid.

the better our results will be. I have tried to use the disodium-monohydrogen-phosphate in various ways and forms to secure its alkalinizing effect upon the system. In every instance, however, the result was an undue cathartic action.

When the formula and composition of the pharmaceutical preparation now known as liquor calcis et sodæ phosphatum compositus was brought to my attention, I felt sure that we had a truly physiologi-

cal pharmaceutical remedy. Its composition per hundred parts of water is as follows: Sodium carbonate (Na_2CO_3),OO.404; sodium phosphate (Na_2HPO_4), 00.023; sodium chloride (NaCl), 00.080; calcium carbonate ($CaCO_3$), 00.057; magnesium carbonate ($MgCO_3$), 00.004; potassium chloride (KCl), 00.004.

When I noted the disodium-monohydrogen-phosphate in conjunction with the other mineral salts, my first thought was that here lies the solution of our dealkalinized cases and the associated disturbance of metabolism. While truly artificial in production, it was evidently so constructed that it could be used as a pretty close imitator of nature's plan.

It contained the true physiological salt in such a combination that it could be introduced gradually, after the plan of nature, and without producing the cathartic effect.

Without saying a word as to my impression of the preparation, I began using it in some very obstinate cases of disturbed metabolism and faulty assimilation, with very gratifying results to the patients as well as to myself. This preparation does not supply the mineral salts thrown away in the fluid in which vegetables have been cooked; neither does it supply the loss of hydrochloric acid, due to defective oxidation of the protein material in the gastric cells. It does, however, supply to the animal economy the special type of sodium phosphate which is absolutely essential to the blood in order to enable the impaired physiological activities to swing the abnormal metabolic processes to those that are normal. It also enables nature to fix the other mineral substances in stable relation to the various structures of the body, and greatly augments assimilative activity.

I first used this solution in a ten months old child who had resisted all forms of change in foods, medicine, and everything ordinarily thought of. At ten months this child was no more advanced than it should have been at five, and it seemed to be steadily losing ground. I advised the substitution of this solution in the preparation of the milk and to give it plain between feedings—making no change whatever in the food. The improvement was surprisingly prompt. Within ten days the child began to thrive, and has continued to do so to this day. After using this preparation in a large number and variety of cases, I became fully convinced that the greater part of its virtue was due to what may justly be called this particular physiological sodium phosphate, and not so much to the calcium and other mineral substances that it contains.

This statement is not made with the intention of underestimating the value of the calcium and other mineral salts that the solution contains, but simply to emphasize the fact that it contains the true and physiological alkalinizer of the animal economy in a form that is practical and that pretty uniformly produces the desired results. While it is true that the sodium carbonate is an alkalinizer, its chief function in the body is in conjunction with the bicarbonate to carry the carbon dioxide from its seat of production to the lungs, at which point the carbon dioxide is cast out of the blood stream into the air sacs and eventually exhaled from the lungs.

As the total amount of this sodium phosphate, required to maintain the full body alkalinity is comparatively small,—not over four or five grams for the twenty-four hours,—a decreased alkalinity can be easily overcome by drinking twenty to fifty ounces of this solution daily. More than this quantity is apt to render the urine alkaline, which is undesirable.

The deficiency in the production of hydrochloric acid can be overcome temporarily by the use of some dilute hydrochloric acid, administered after meals. The taking of an alkali before the meal will in a measure overcome the acidity of the alimentary canal, which is due to fermentation of the food stuffs made possible by the absence of the hydrochloric acid and digestive ferments. An alkali taken before the meal, further, seems to stimulate the gastric secretion; and secondarily increases the oxidation reduction of the proteid material in the gastric cells. Some form of light laxative must be used to make good the decreased production of the sodium sulphate.

In those instances in which there is a decreased production of the taurocholic acid, which is another factor in producing and keeping up the disturbances in metabolism and non assimilation, something must be done to reestablish the full amount of oxidation reduction of more proteid material by the liver cells. There are various methods by which this can be accomplished. Sometimes one method works best, at other times an entirely different therapeutic agent will be required.

When all these abnormal conditions have been recognized and corrected along truly scientific lines, we can almost inevitably obtain pretty exact and perfect results.

THE CONTROL OF HYPERCHLORHYDRIA AND ITS CONSEQUENCES BY CHOLECYSTO-GASTROSTOMY.*

By W. WAYNE BABCOCK, M.D.,
PHILADELPHIA.

ANY rational method for the control of hyperchlorhydria must have a basis in sound physiologic fact. This is as true of an operative treatment as of the treatment by diet and medicines.

The activity of pepsin in the stomach depends upon its combination with hydrochloric acid which is formed by the parietal cells of the gastric glands in the prepyloric portion of the stomach. The acidified pepsin mixed with food is carried by peristaltic waves to the pyloric antrum, a part which is subjected to a more intense irritation from the gastric juice than any other portion of the stomach. Evidently, to protect the antrum from digestion, we find that its mucous glands contain no parietal cells and secrete an alkaline mucus, while normally at the completion of gastric digestion the pyloris relaxes and a reflux of bile and pancreatic juice into the stomach rests the antrum from the erosive chyme. In the duodenum there is also an interesting protective mechanism. The acidified pepsin, if permitted a prolonged contact, might damage the intestinal mucosa but this is prevented by the closure of the pylorus (Cannon), which is produced reflexly on the entrance of acid chyme into the duodenum and which continues until the acid is neutralized by the bile and pancreatic juice. The neutralization is more than a mere change in reaction, it is an absolute destruction of the ferment, for acidified pepsin once neutralized is rendered permanently inert.

Points on the mucosa where the protective mechanism is weakest are the predominent sites for peptic ulcers. Thus the ulcers in the stomach are found chiefly on the upper and lateral walls of the antrum where there is the most prolonged contact with the most acid gastric juice associated with the most intense motor activity. The duodenal ulcers are most frequently on the upper wall of the first portion just where the spurts of acid chyme through the pylorus first impinge and where neutralization is most difficult. In the fundus of the stomach which serves to store and hold the food awaiting digestion and where there is little acid secretion or active gastric juice, ulcer is rare, although not as rare as in the well neutralized second and third portions, of the duodenum and the jejunum, where ulcer is almost unknown. If we permit the active gastric secretion to enter directly a practically immune portion of the upper digestive tract, erosion and ulcer frequently occur and precisely at the point where the acid secretion first enters the bowel. Thus from gastrojejunostomy a jejunal ulcer occurs in about 2 per cent. of the cases. Clinically the most effective medical treatment against peptic ulcer is the reduction of the hyperchlorhydria by rest, the use of a diet that either does not stimulate the secretion of hydrochloric acid or that will promptly combine with the secreted acid, perhaps associated with the very free use of alkalies.

Unquestionably such a treatment in many cases controls the hyperchlorhydria and gives the patient complete relief from the symptoms of ulcer, but unfortunately the relief usually is not permanent, and a considerable percentage of the patients finally seek relief through operation.

Of the surgical operations, all that have won any wide degree of acceptance permit the neutralization of the gastric juice by the regurgitation of bile and other intestinal secretions into the stomach. This occurs, for example, in gastroenterostomy and the various forms of pyloroplasty. When the neutralization of the chyme bathing the ulcer is less complete the results of the operation are less satisfactory. Thus in duodenal ulcer a gastroenterostomy usually relieves; the bile and pancreatic juice enter the stomach through the new stoma, reduce the acidity of the chyme passing through the pylorus, and the ulcer heals. In these cases *x*-ray studies may show that no food leaves the stomach by the new opening, proving that the benefit is not derived from any new or better drainage. If the pylorus is occluded the ulcer heals a little more surely as it is then completely protected from the acid gastric juice. With gastric ulcer the results from gastroenterostomy are poor; the ulcer is usually along the upper part of the antrum and the bile entering the stomach at a dependent part is swept on by peristaltic action to the pylorus and does not efficiently neutralize the chyme bathing the ulcer.

Part of the value of a "coat sleeve" resection of the stomach may be from bringing the cardia closer to the pylorus so that the bile normally entering the stomach when the pylorus relaxes has easier access to the cardia and to what remains of the lesser curvature.

Pyloroplasty and the Finney operation, of course, provide a means for the more complete and continuous regurgitation of bile into the stomach than is normal.

If peptic ulcer selects for its seat points where there is the most prolonged and intense hyperchlorhydria, if the ulcer rarely occurs on alkaline mucous surfaces, and if it heals when the acidity is overcome by admixture with the normal antacid bile, it is evident that acid pepsin is the most important single factor in the production of ulcer. Such being the case, why not simplify the surgical problem by throwing the bile directly into mucous areas that have proved unable to withstand the acid gastric juice and thus produce a continuous physiologic neutralization of the affected mucosa? Why not do a cholecystogastrostomy for obstinate hyperchlorhydria, or what we would term a cholecysto-ulcerostomy for ulcer, anastomosing the gall bladder with the edges of the opening left after an ulcer excision, or so placing the anastomosis that bile continuously bathes and protects the ulcer-bearing area? Of itself the entrance of bile into the stomach produces no harmful symptoms, normally entering the stomach after each meal, frequently being found in extracted test meals, and almost continuously entering the stomach after gastroenterostomy with complete digestive comfort. Years ago Moynihan reported the case of a boy shot through the jejunum—for whom he closed the ends of the divided bowel and did a gastroenterostomy. This boy, although all of his bile and pancreatic juice had to pass through the stomach, and out

*Read at the annual meeting of the American Therapeutic Society held in Philadelphia, May 8, 1920.

through the new opening, developed normally and remained free from digestive symptoms.

In about 27 cholecystogastrostomies, and 15 cholecystoduedenostomies, I have seen no ill effect *per se* from the operation. In gall-bladder disease I was first impressed by the rapid and early convalescence and the relief from indigestion that followed the operation. In a series of 10 gastric or duodenal ulcers if we exclude one neurotic woman who had had 13 abdominal operations, and one patient dying from an associated condition, the results thus far have been excellent. In these patients the symptoms apparently have been relieved, and in one case of bleeding ulcer there has been no hemorrhage since the operation, and the patient has rapidly gained in weight and is free from his old dyspepsia.

The operation is simpler and easier than a gastroenterostomy and may be performed through a smaller incision and with less manipulation or exposure of intestinal contents. It is not difficult to do under local anesthesia. We have performed it under local anesthesia in a number of very old, obese, weak, or toxic patients, or those with bad myocardial disease. It seems to do for ulcer in a simple and direct way what other operations do in a roundabout and rather illogical manner.

We make a fairly large opening (2 to 4 cm.) in the long axis of the stomach and use a rather broad area of anastomosis with two or three rows of 00 or 000 chromic catgut. The gall-bladder, usually, can be sufficiently mobilized to be brought to the desired part of the stomach. As a rule no drainage is used and the wound is tightly closed. After the operation the gall-bladder probably gradually contracts to a small duct. In a few *x*-ray and clinical studies after operation the bismuth meal has not entered the gall-bladder, and while hydrochloric acid was at times present in the contents it was in less than the normal amount and associated with a diminished total acidity.

It is to be appreciated that this is but a preliminary report of an operation, made with an enthusiasm that comes with a limited and rather recent experence. It is hoped that the operation may be sufficiently tried to prove or disprove soon our early good impressions. If we can eradicate the chief cause of ulcer of the stomach we have also gained a most important point in the prophylaxis of cancer of the stomach when it is recalled that cancer as a rule springs from mucous surfaces in contact with an acid secretion.

2033 WALNUT STREET.

THE TREATMENT OF SYPHILIS.

BY WALTER J. HIGHMAN, M.D.,

NEW YORK.

ASSOCIATE PROFESSOR OF DERMATOLOGY AND SYPHILIS, NEW YORK POST GRADUATE SCHOOL AND HOSPITAL; ACTING ASSOCIATE DERMATOLOGIST, MT. SINAI HOSPITAL, NEW YORK; ADJUNCT DERMATOLOGIST, LENOX HILL HOSPITAL, NEW YORK.

ALTHOUGH a great deal has been written on this subject, it is permissible from time to time to review even well known principles in order to fix them more securely in mind. Obviously there can be no standard method of handling any disease and every physician, as a result of his peculiar experience, finally works out for himself a system which satisfies his own point of view. The introduction of synthetic arsenic compounds ten years ago revolutionized our point of view as to the treatment of syphilis and promoted a clearer understanding of the disease.

This arsenic compound is arsphenamine, and to-day there are several brands of the substance (Schamberg's, Metz's, Billon's, Takamina's) differing from each other slightly as to their physical attributes, but all about equally efficacious therapeutically. Any one of these brands that has passed the test of the Hygienic Laboratory in Washington can be employed with safety. Arsphenamine must be regarded as an artificially produced antibody. It destroys spirochetes because the arsenic in the molecule is attached to the microorganism by the benzol ring, the latter roughly corresponding to an amboceptor. When this union is complete the arsenic exerts its destructive effect upon the germ, which is disintegrated, and thereupon unloads upon the host the poison which had previously been confined within the cell body of the parasite. The reason for alluding to this fact will become clearer later on. It must be remembered that arsphenamine works specifically upon the parasite and not upon the host. Nevertheless more than a certain amount of arsphenamine is poisonous to the patient. Therefore the theoretical aim in employing a compound of this sort is to inject more than enough necessary to destroy all of the parasites, but not nearly enough to poison the host. In spite of all precautions, however, some people are hypersusceptible to the drug and present symptoms of poisoning after its administration. This poisoning may be due either to the arsenic or to an unknown substance in the compound or to the improper preparation of the substance.

In order to prepare arsphenamine properly it is necessary to employ sterile glassware, sterile rubber tubing, sterile needles, and sterile, freshly distilled water. The average safe dose per injection is four decigrams (0.4) but most people are able to tolerate six decigrams (0.6) and the optimum bulk of water in which the substance is injected has been found to be twenty cubic centimeters per decigram. Thus a total bulk of four decigrams would be eighty cubic centimeters of water, and for six decigrams one hundred and twenty centimeters. An ampule of arsphenamine is emptied into a sterile flask and about thirty cubic centimeters of hot sterile distilled water are added. The container is gently agitated until the powder has gone into solution. The fluid is now clear yellow or brownish yellow, but is acid. In this acid state it is highly poisonous and it must be neutralized before it is safe to inject it. This is accomplished by adding about fifteen drops of 15 per cent. freshly made up sodium hydrate solution. The fluid now becomes opaque because a precipitate forms which is an insoluble salt of arsphenamine. If this emulsion were injected the patient would be killed by embolism. It is necessary to continue to add sodium hydrate drop by drop until a clear solution is again produced. At this point the solution is slightly alkaline. By adding from two to five drops more of the sodium hydrate, in other words, by produc-

ing a slight over alkalinization a disodium salt is formed which is prevailingly not toxic. The solution is again clear and yellow but it is still too concentrated.

We now come to the second step in preparation. A sterilized, graduated glass container has been suspended from the wall, about two and a half feet above the level of the operating table. In its upper end has been placed a sterile glass funnel containing sterilized cotton. At the lower end of the container is a sterile soft-rubber tube, about a yard long, at the end of which is an adapter to fit the needle. About three inches above the adapter is a clamp. About two ounces of sterile, distilled water is poured into the container and the air in the container and rubber tube is exhausted. The water is let down to the zero mark. Arsphenamine solution is now poured into the funnel and it filters through the cotton. More sterile distilled water is added until the container holds a total bulk of eighty centimeters of solution or one hundred and twenty centimeters, according to whether four or six decigrams of arsphenamine will be used.

The patient is now ready for the injection. A tourniquet is placed around the biceps closely enough to make the veins stand out, but not tight enough to obstruct the arterial circulation. Obviously the patient is lying down. The needle is gentle inserted into the patient's vein and when the blood flows freely the tourniquet is removed, the tubing is fitted into the needle, the clamp is released, and the arsphenamine is allowed slowly to flow into the vein. The speed of the injection must not be too great or the patient may go into collapse.

It will be seen that there are some technical complexities in the use of arsphenamine. For the physician properly equipped for this work these factors are of no moment, but for practitioners not thus equipped or whose practice is not largely among syphilitics the aforementioned difficulties may seem insuperable. There are two ways in which the difficulties may be overcome. One is by the use of neoarsphenamine which needs no alkali and which may be injected in greater concentration, and by using an ordinary twenty centimeter syringe. The dose of neoarsphenamine must be half again as great as that of arsphenamine, since the salt is less efficacious. The other simplification has been furnished by the recent success of a pharmaceutical house in the manufacture of a permanent solution of arsphenamine. At the last meeting of the American Medical Association, Dr. Stetson of New York, in his discussion stated his experience with this solution, and he found it therapeutically as efficacious as the solution made in the physician's office and no more toxic. This solution is prepared in the Lowy Laboratories, and has been licensed by the Hygienic Laboratory. Any brand of arsphenamine specified by the physician is supplied in permanent solution, ready to use, with all the appurtenances for administration sterilized and included in the package. I have given sixty injections with this solution and can corroborate Dr. Stetson's statements. Each package is dated by the order of the Hygienic Laboratory and the substance should not be used after the date specified.

Undoubtedly it would be desirable if every physician could prepare his own solution, but this is not possible in smaller communities, nor even in larger communities among practitioners who do not frequently have reason to employ the drug. For men in these groups a permanent solution is of great advantage.

In addition to arsphenamine, mercury must be employed in the management of syphilis. This is done in three ways. Either by mouth, by inunction, or by injection. The disadvantage of the first method lies in the irritation of the intestinal tract; the disadvantage of the second is that it requires a great deal of time, is usually done carelessly, and is unpleasant; the disadvantage of the third method is due to the fact that if mercury poisoning develops there is no way of suddenly interrupting the treatment as is possible when the first two methods are used. In spite of everything, however, the injection method is the cleanest, quickest, and most efficacious. Thus this is the one advocated by the author. Either soluble or insoluble salts may be employed. The latter group is the more efficacious, and of these mercury salicylate is the most useful. According to the work of Harold Cole of Cleveland, mercury salicylate is the most easily absorbed of the insoluble compounds. It is prepared in 10 or 20 per cent. emulsion in sterile olive oil to which 1 per cent. of liquid petrolatum has been added. The injection is given every five or seven days beginning with a half grain. The tolerance of the patient is determined by increasing the amount until salivation develops. Two-thirds of this amount is then used at each injection, for there is no advantage in producing mercurialism. The iodides are a useful adjuvant in treatment. The saturated solution is administered after meals three times a day. A great many people are unable to stand iodides. They either get symptoms of congestion in the upper respiratory passages, or the iodide acne. If this should develop the drug must be interrupted.

The symptoms of arsphenamine poisoning vary. Many untoward results can be avoided by cautioning the patient not to eat before the injection, and to partake of food only sparingly during the few hours following it. Sometimes, and particularly after the third, fourth, or fifth injection, the patient suddenly turns blue, his face swells, the pulse gets weak and rapid, and it is hard for him to breathe. This picture suggests anaphylactic shock. In patients known to be subject to this, the attacks can be prevented by injecting hypodermatically 1-50 of a grain of atropine ten minutes before the arsphenamine injection. Furthermore, the attack can be controlled by injecting seven drops of suprarenal gland extract. A common picture of arsphenamine poisoning comes on from three to ten hours after the injection. This is characterized by pain in the bones and joints, headache, vomiting, and diarrhea. The rarer forms of poisoning present the symptoms of acute jaundice, chronic jaundice, or a chronic, itching, red, scaling disease of the skin which lasts for several weeks and is often accompanied by nephritis. The mild skin disturbances that occur are eruptions that look like scarlet fever or measles, and some forms of herpes or even zoster. Death from arsphenamine is extremely rare.

When the substance was first used, numerous

cases were reported of partial or complete blindness or deafness. These were supposed to be due to the drug, but it was found that this was not so and that the untoward results were due to syphilis itself. If a fresh case of syphilis is treated with arsphenamine or mercury, it has been observed that the rash grows brighter and more intense. This is caused by the destruction of the parasites and the local outpouring of their poisons which increase the inflammation. This is called the Herxheimer reaction. If a similar process takes place in a nerve the function of the nerve will be impaired. It is this phenomenon that caused the blindness or deafness alluded to above, and the proper thing to do is to continue the treatment of syphilis and not to stop it. Since we have become familiar with this fact the disturbances just discussed have become rarer. These disturbances are called neurorecidives.

Syphilis should not be treated continuously but rather in interrupted courses. This is due to the fact that the parasite becomes accustomed to the drug and is no longer destroyed by it. It is better to combine arsphenamine and mercury in courses, giving from six to twelve injections of the former, and from ten to fifteen of the latter. In late syphilis iodides may be added. It has been found recently that it is safe to use arsphenamine every four days, but for ordinary purposes it is sufficient to make the interval from five to seven days. Thus, the patient would get one arsphenamine injection every fifth or seventh day and one mercury injection at similar intervals, the total series covering a period of from eight to fifteen weeks. Two or three series should be administered annually.

The object of treatment is to make the symptoms of the disease disappear, and to turn the Wassermann test from positive to negative. It would require a separate paper to discuss the value of the test, but for practical purposes the latter may be regarded as one of the signs of the disease, without the disappearance of which, the patient cannot be considered cured. The treatment differs in different stages and phases of the malady.

In the primary stage, before the Wassermann test has become positive, the patient should receive two courses of treatment in the first year and only mercury in the second and third years, provided the Wassermann reaction never develops. In primary syphilis with a positive Wassermann test the patient should receive two courses of combined treatment in each of the first two years and only mercury in the third year, provided the Wassermann test has become and remains negative. The same is true in secondary syphilis. In older syphilis the patient should receive at least three years of combined treatment including iodides, but the use of arsphenamine should not be stopped in late syphilis until the Wassermann test has become negative, no matter how long it takes.

There are several exceptions to this rule. A man of sixty does not require as intensive treatment for latent syphilis with a positive Wassermann test as a man of forty or twenty would require, because there is a smaller margin of time ahead of him in which the complications of the disease can develop.

There are a few fine points to be emphasized. In treating syphilis of the heart, blood vessels, and kidneys, it is inadvisable to start very intensively, because a sudden resolution of the syphilitic process might cause permanent damage to the organs or even death. Thus it is well to start such patients off with a course of iodides and mercury over a period of two or three months. Then arsphenamine administration may be begun.

The problems of treating syphilis of the central nervous system are too numerous to be discussed in this paper, which purposes to deal more with the disease in its general manifestations, but it may be stated that at times it is necessary to add to the general treatment of the disease the subdural introduction of arsphenamine according to the combined method of Swift and Ogilvie.

The great problem is to know when the patient is cured. The earlier in the course of the disease treatment is begun the prompter the cure. Thus in the primary stage, before the Wassermann reaction, we find the optimum time. Theoretically we may say that if a patient has been free from symptoms and signs of the disease for a year without treatment, if he presents no Wassermann reaction, and if the cerebrospinal fluid is normal, he is well. The difficulty is to know when to start the test year. It is impossible to lay down any definite rules, for each case must be judged on its own merits, and even those with the greatest experience must inevitably make mistakes. But it is safe to say that the test year should never be begun before at least three years of treatment have been carried through conscientiously. During the test year the patient should be examined every two months, the Wassermann test being made each time. And at the end of the year, as well as at the beginning, there should be an examination of the spinal fluid. Annually for six years after the test year the patient should be thoroughly examined both physically and serologically.

It is hoped that this brief outline of the management of the disease will serve to convey to some a few of the cruder standards which are of use in the treatment of the malady and which may serve as guides in controlling the progress of treatment.

THE GUILLOTINE, A SIMPLE ONE-MAN INSTRUMENT FOR DOING CIRCUMCISIONS.

By CHESTER T. STONE, M.D.,

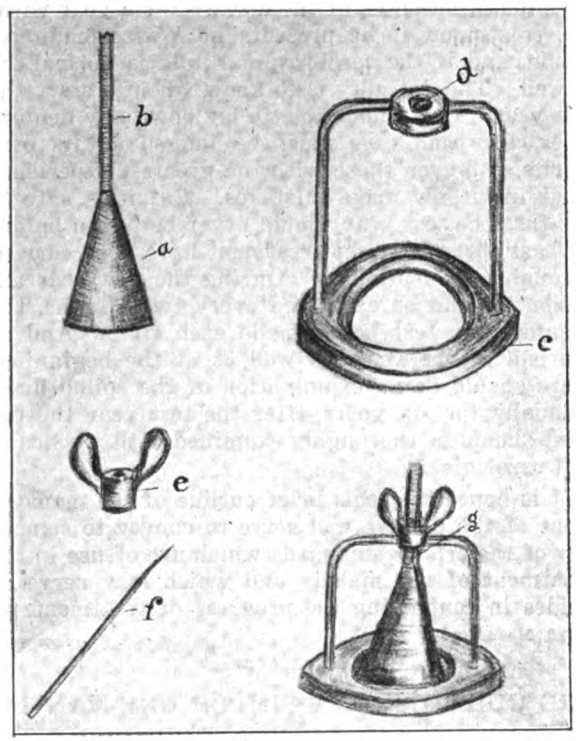
BROOKLYN, N. Y.

How true it is that there is nothing new under the sun. New applications of old principles are, however, constantly occurring. Being greatly hampered by lack of assistance during the war prompted the devising of this instrument.

It consists, as may be seen in the cut, of a cone (a) continued at its narrow end to a screw (b); (c) a plate with a hole the exact size of the cone at point of contact, the inner edge of the plate being a knife. Bridging the plate and bisecting the hole is a bridge (d), perforated for the passage of the screw; (e) is a winged nut for drawing the cone against the knife, and (f) a pin for rotating the cone in case of need. The instrument comes in five sizes from that suitable for an infant up to a large adult size.

To perform the operation the instrument is taken

apart and the cone lubricated on its inner surface, placed over the head of the penis after first retracting the foreskin. The skin is next pulled over the outside of the cone. It is well at this time to mark the skin with a pen at the point where it is to be removed. The cutting plate is next placed over the cone and skin with its edge in contact with this line; the winged nut is then screwed down until there is slight pressure on the skin. Now the local anesthetic may be injected just posterior to the inked line. When sufficient time has elapsed for the anesthetic to be effective, tighten up on the winged nut until a click is heard. With this the skin may be seen to roll up on the cone. Remove the clamp and suture. The incision will be found to be smooth and clean-cut, with no tabs or buttonholes or bulging frenum. In some cases of unusually thick mucous membranes the skin will cut through but the mucous membrane may remain in-



The guillotine for circumcision operation.

tact at intervals. By loosening the winged nut two or three turns and inserting lever (f) in hole (g) a rotary motion may be given the cone and the mucous membrane may be severed. The plate is so beveled that a knife may be used if preferred. After tying the bleeding vessels the most effective method of suturing seems to be to first place four sutures anterior, posterior, and lateral, leaving the ends long for binding on the dressing. By placing tension on two adjacent ones as anchor sutures, a continuous suture is then run around the whole edge. The result will be most pleasing.

Aside from the fact that this instrument makes the act a one-man operation, it has many other advantages. It is quicker, the author having done five complete operations, including the anesthetic and suturing, in one hour. It is practically bloodless, for the compression makes an efficient hemostat. The cosmetic results are far ahead of any method, for with this instrument it is impossible to have eight pointed stars, unsightly bulgings, or unforgivable buttonholes. The instrument is practically "fool proof," which is a decided advantage. It will be noted that less anesthetic has to be used on account of pressure anesthesia produced by the clamp. The wound will also heal more rapidly than it does when other methods are employed. The instrument itself is easy to keep in shape and can be used by anyone. Its use might be compared to the way some people play billiards. For starting an operation with this instrument there are always three ways of making a shot, either by pressure, by rotating the cone, or by using a knife.

62 PIERREPONT STREET.

Medicolegal Notes.

Medical Testimony as to Surgeon's Care and Skill Admissible.—In an action against a physician and surgeon for negligence in performing an operation, where the plaintiff's declaration expressly charged want of care and skill, the testimony of other surgeons that the defendant was a careful and skillful surgeon was held admissible.—Shaw v. Klein, Mississippi Supreme Court, 83 So. 620.

Extent of Liability.—The Minnesota Supreme Court says, by way of obiter dictum, that a physician or surgeon "is not necessarily liable for malpractice because of a bad result. He must often act promptly, upon his best judgment, and he is not liable for injuries arising, without negligence, from honest errors of judgment. But this is an exception to general rules of negligence and the exception is not absolute. Every act of his is in a sense an exercise of judgment and usually of honest judgment. Yet it may be negligent. He might be honest in his judgment that he could safely leave certain details to an assistant and yet be liable for negligence in doing so. . . . If a surgeon persists in the use of an anaesthetic after warning which would impel one of reasonable prudence to desist he should be held to answer for the consequences."—Moehlenbrock v. Parke, Davis & Co. (Minn.), 176 N. W. 169.

Insufficient Evidence of Failure to Diagnose.—In an action against a physician for malpractice, where the basis of the action was failure to diagnose as cerebrospinal meningitis the affliction from which one child in the plaintiff's family was suffering, and that defendant allowed other children to mingle with the one afflicted so that they contracted the disease, it was held that the evidence as to the presence of cerebrospinal meningitis was insufficient to warrant the submission of the case to the jury, and judgment for the defendant notwithstanding verdict was directed. It was also held that an uncalled for statement by the plaintiff's counsel in his argument to the jury that the physician was protected by insurance was error necessitating reversal.—Sherwood v. Babcock, Michigan Supreme Court, 175 N. W. 471.

Classification for Taxation of Physicians According to Length of Practice Is Discriminatory and Invalid.—The Arkansas Supreme Court holds that a classification of physicians for taxation under the State statute of 1919, authorizing cities to tax occupations, by imposing a greater tax on those who have practised ten years or longer than on others, violates the provision of that law that "no classification shall be based upon earnings or income." The court says that it is difficult to see how men of the same learned profession can be put in different classes for purposes of taxation, except upon the basis of difference in earning capacity or income, and any other classification would be purely arbitrary. The discriminatory effect of such an ordinance can, however, be eliminated by striking out the excessive amount of the tax without affecting the validity of the ordinance in any other respect.—Davies v. City of Hot Springs (Ark.) 217 S. W. 769.

INTUSSUSCEPTION IN TYPHOID FEVER.

IF one may judge by the number of reported cases, intussusception in the course of typhoid fever is an extremely rare complication, but a very deadly one when it does occur unless recognized early and properly treated. Recently A. L. Moreton (*British Journal of Surgery*, April, 1920) has reported a new case and reviewed the literature. As he says, the rarity of the condition may be estimated from the few references that are made to it in the standard textbooks on medicine and surgery. Thus, Murchison's classical treatise "On the Continued Fevers of Great Britain" makes no mention of it, while the same is to be said of Allbutt's "System of Medicine," 1905, and Nothnagel's "Encyclopedia of Practical Medicine," 1904; Osler and McCrae in "A System of Medicine," 1907, simply say that several instances have been reported, in one with hemorrhage, the diagnosis of perforation being made; while W. W. Keen makes no mention of the matter in his classical volume on "Surgical Complications and Sequelæ of Typhoid Fever," 1898.

In Moreton's case the patient was a woman 24 years of age. Up to the forty-seventh day the course of the disease had been moderately severe with some atypical features, especially as regards constipation and the character of the temperature, which had been rather of the remittent type. On the morning of the forty-seventh day the temperature suddenly fell to 97.8° and the patient had a severe attack of vomiting. The pulse rate was not raised, abdominal distention was not increased, the area of liver dulness was normal and the abdomen moved well on respiration. On the afternoon of the next day the pulse rose from 120 to 140, the temperature remaining about the same, while there was colicky pain in the right iliac fossa. On the forty-eighth and forty-ninth days the bowels moved spontaneously and no blood was found in the stools, while the blood count showed but a very slight leucocytosis. On the afternoon of the forty-ninth day pain had become very acute, the right iliac fossa was exquisitely tender and an ill-defined, resistant mass was found on examination, while the abdomen was becoming distended. Perforation and various other possibilities were thought of (apparently not intussusception, however) and an exploratory operation was decided upon. Ileo-ileal invagination was found, the apex passing into the cecum, but without participation of the ileocecal valve or appendix. The intussusception was easily reduced and no cause, such as a swollen Peyer's patch, could be found. The subsequent course, as far as postoperative features were concerned, was uneventful and the patient was ultimately discharged cured.

Moreton was able to find but ten other cases in the literature, one of which occurred in a two-year-old infant, the average age of the others being 21. Five of the patients were males, three females, and in three the sex was not stated. The period of the disease in which intussusception occurred was noted in eight cases: One in the first week, one in the second, one in the fourth, two in the sixth, and three in the seventh week. The intussusception was enterocolic in six cases, enteric in three, and in two the type was not recorded. In two of the enteric cases there was more than one intussusception. Of the eleven cases, six recovered, four died, and in one the result was not stated. Operation was done in six cases with but one death, that being in a case with three intussusceptions, all ileo-ileal.

Summarizing his study of these cases, Moreton says that acute intussusception is one of the rarer complications of typhoid fever; it may occur at any time during the progress of the disease, but it is usually late in its course or during a relapse; it may be caused by irregular peristalsis due to inflammatory changes in the wall of the gut, or an enlarged Peyer's patch may start the process; the type is more commonly enterocolic, and if of the enteric there may be more than one lesion; the differential diagnosis from perforation may be difficult; the prognosis is good with operation, and operative results are much better than in cases of perforation; and in reducing the intussusception it should be borne in mind that diseased bowel is being dealt with, and the utmost gentleness should be used in all manipulations.

IMPORTANCE OF DISEASED BRONCHIAL GLANDS.

OUR knowledge of enlargement of the lymphatic glands during life is for the most part dependent upon our ability to palpate them. Any well-performed physical examination always takes into account the glands of the neck, groin, axilla, elbow, etc., and their condition is set down with a certain feeling that we have been thorough in our work. Unfortunately, however, there are large groups of highly important glands in both the abdomen and thorax which never come under the searching finger. Those in the abdomen are made a little more accessible through operations; but the thoracic glands may be greatly enlarged and diseased without our having suspected it during the life of the patient. Now and then *x*-ray

plates of the chest bring out with some degree of precision certain shadows which are taken to be mediastinal glands, but one is never quite sure about them until autopsy.

Writing in the *Acta Laryngologica*, Vol. 1, Fasc. I, Prof. E. Schmiegelow of the Rigshospital, Copenhagen, Denmark, makes a contribution to the pathology of the bronchial glands, laying, of course, especial stress on tuberculosis. The diagnosis, he says, can be made in three ways: By direct bronchoscopy; visually, by the patient coughing up the gland; and by post-mortem. To many practitioners this will not offer much hope, especially the post-mortem cases. Coughing up the gland takes place only in those instances where a caseous gland has ruptured into the bronchus, in which case pus may flood the lung and death ensue promptly. Now that direct inspection of the bronchi has become a well-established procedure, it may be of benefit to submit the patient to a bronchoscopist for his opinion, but in many instances, particularly in children, parents will rebel even though it can be shown that no possible harm can result—a statement which few specialists would care to make over their own signatures.

But to revert to the more academic aspect of the matter, Schmiegelow states that 8 per cent. of healthy bronchial glands in healthy individuals contained tubercle bacilli. This he quotes from Kälble. In children the enlarged glands are mostly tuberculous in origin; in adults they are anthracotic or calcareous, which may mean that they have been tuberculous. Perforation into the bronchi, either potential or actual, is described by various writers in from 0.3 per cent. to 3 per cent. of all autopsies. Perforation in children causes violent choking spells, even death. Persistent cough without much sputum is caused by the glands irritating the vagus or by pressure on the easily compressible bronchial walls. Where sudden death occurs in children afflicted with enlarged and diseased bronchial glands, the question immediately assumes a medicolegal aspect. Thus Reunert cites the case of a child left playing by itself without any guardian near at hand. The child had been quite well. When the parents came to take it away they found the little one dead. Violence was suspected, but autopsy showed that the child had died of suffocation following perforation of an abscessed bronchial gland into the lung. If the perforation is small the gland is discharged slowly, if the perforation is large the destructive lesion is large and the patient drowns in his own secretions.

Diagnosis and treatment by tracheobronchoscopy has been successfully carried out, but it is at present possible only in glands situated in the posterior mediastinum. Treatment by internal medication is disappointing. There are cases both in adults and in children where a violent, non-productive cough has tried the nerves of doctor, patient, and everybody concerned. Inhalations, deep intratracheal injections of silver salts and other mucous membrane antiseptics, cough medicines, alteratives, such as the iodides, and all other efforts avail nothing. The thoracic glands are probably infected and enlarged in such a case, and nothing short of a change of climate will suffice. An ocean voyage or balmy pine-laden air may help to shorten the course of the malady.

As for the anterior mediastinum, J. K. Dalziell has reported three patients from whom he removed the sternum. In one he found an abscess under the arch of the aorta. Caseous tuberculous glands were discovered and removed, and the patient recovered.

The importance of the whole matter seems to lie in the diagnosis of the kind and degree of bronchial gland involvement. In children we may expect cough and difficulty of getting the air in and out of the bronchi. Papillomata of the airways must be ruled out and one is probably rarely justified in making a diagnosis of "asthma" in these little patients. In adults we must remember the possibility of bronchial gland enlargement coincident with any infection of the airways or adjacent lymph paths. Auscultation and percussion will tell us little, the *x*-rays more, and the bronchoscope most. Ultimately we may have to send the patient away, and then our major effort is centered on just what the right climate is likely to be. That is not infrequently experimental for each individual. Shall it be the mountains or the seashore or the pine woods? Even in the presence of frank pulmonary tuberculosis, the answer is not always easy.

THE DIAGNOSIS OF SYPHILITIC CHANCRE OF THE PALPEBRAL CONJUNCTIVA.

SYPHILITIC chancre of the palpebral conjunctiva when fully developed remains stationary for a lapse of time varying from one to two months, after which cicatrization takes place in the usual way without leaving any apparent trace of the sore. The diagnosis of the lesion is difficult, particularly so because the true nature is not suspected, and frequently it is not until the advent of the secondary manifestations of syphilis that the diagnosis is made. Mistakes are more prone to be made at the onset of the lesion when symptoms are still absent. Later, when the process has arrived at the stage of a painless ulcer, with an indurated base with edges unelevated and accompanied by a tumefaction of the preauricular lymph node — hard, painless, and movable — the diagnosis is easier. Although it is impossible to make the diagnosis from the clinical aspect of the lesion, when fully developed at the end of three weeks, the Wassermann will probably be positive and the treponema can be found in scrapings made from the surface of the ulcer.

The differential diagnosis must be made from conjunctival tuberculosis, epithelioma, ulcus molle, secondary and tertiary luetic lesions, and other oculopalpebral affections, such as herpes, stye, and chalazion. Tuberculosis of the conjunctiva is more common in children and young

subjects with a tuberculous history; rarely a primary localization, it is more frequently a secondary lesion from extension of lupus on the nose, nasal canal, or lids. The ulcer has a dirty, gray fundus with irregular edges, its base is not indurated, while around it small grayish-yellow nodules are seen. Epithelioma is met with in elderly adults. It forms a reddish growth of variable consistency with a rather irregular surface bleeding readily. It is not uniform in color, being a dirty red and granular in spots. Enlargement of the lymphnodes occurs late in the process. Simple ulcus molle is so rare on the conjunctiva that its reality has been doubted, but some authentic cases have been reported by both Gaston and Vignes. The lesion is painful, with red, undermined punched-out edges, and an irregular grayish yellow fundus. The enlarged lymphnodes are painful and the specific bacillus can be found in the secretions from the sore. Mucous patches of the conjunctiva never produce tumefaction of the lymphnodes and are not indurated. They are accompanied by other secondary manifestations. Syphilitic tarsitis is a late symptom of the infection and has a painless evolution. The tumefaction involves the entire lid and the tumor remains localized to the tarsus. Gummata of the palpebral conjunctiva are extremely rare, far more so than on the bulbar conjunctiva. Out of twenty-five cases collected by Bayard in his thesis (Paris, 1895) the palpebral conjunctiva was the seat of the process in only five. In gumma, the ulceration is much deeper, extensive and sanious. The history of the case, absence of enlarged lymph nodes, and the rapid action of potassium iodide differentiate a gumma from a chancre. There is no lymphatic involvement in stye and it has a painful inflammatory evolution, while in conjunctival herpes there are pain, intense photophobia, and intact lymph nodes. Chalazion is round, hard to the feel, rarely ulcerates, and has granular contents.

It is clear, therefore, that the main difficulty in making the diagnosis is that the primary sore of syphilis on the palpebral conjunctiva, because of its infrequency, does not occur to the mind of the observer.

THE UPSTREAM SPREAD OF CHOLERA.

In 1883 the British Government sent a cholera commission to Egypt to study an epidemic of the disease which spread from the Damietta mouth of the Nile, where that river falls into the Mediterranean, to the place where it divides into the Damietta and Rosetta branches, thence up the main river. Cantlie, who was a member of the commission, called attention to the fact that the infection spread from town to town and district to district, until its track was lost somewhere about the Dongolo district. The towns in the Rosetta branch and the Delta were irregularly attacked, showing, as Cantlie believed, overland infection in all probability. The upstream spread of infection he attributed to fish, but has had no opportunity of investigating this supposition. These views, which he recalls in a note in *The Journal of Tropical Medicine and Hygiene* (August 2, 1920, p. 198), are of particular interest just now, in view of the reiterated prophecy that cholera, among other alien diseases, may invade this country and others to which it is unfamiliar. Cantlie's suggestion that Hoops, who contributes experiences with this disease as seen in a new country (Kedah, Malay Peninsula) (*ibid.* p. 189), might take up this question is pertinent, and applies likewise to other investigators.

Hoops, in the contribution mentioned, calls attention to the suggestion that the cholera outbreaks in Kedah were not due to imported cases, but to the persistence of the cholera vibrio in the country between the epidemics, either in an altered and unrecognizable form (temporarily nonpathogenic) in the earth or water, or in the gallbladder of human carriers. It is certain, he states, that to infect man the cholera vibrio must be swallowed. Answering the question as to the channels by which it spreads, Hoops accepts the view that it is largely by the same agencies as those by which typhoid fever is disseminated, namely, food, fingers, and flies. Among other possible food sources of infection are mentioned fish from infected rivers, the eating of which has been condemned by Gimlette, and shellfish scraped from the bottom of ships, which have been found to contain cholera vibrios.

If these possibilities are proved to be in line with the suggestion of Cantlie, the upstream spread of cholera is no more difficult of explanation, as some have thought, than spread in any other direction from the apparent point of origin.

FAMILIAL DEMENTIA PRECOX.

Laignel-Lavastine discussed this subject at a recent session of the Société de Psychiatrie, reported in *La Presse Médicale* for June 2, 1920, xxviii, 36. The author presented before the society a brother and sister, both attacks with progressive psychic dementia with lack of insight, disorientation, apathy, grimaces, and assumption of meaningless attitudes. The brother showed more mutism and inertia while the sister showed more excitement with attacks of laughter, puerilism, and timidity. The diagnosis was hebephreno-catatonic form of dementia precox which appeared in the boy at the age of 18 and in the girl at the age of 12. The father was an alcoholic and probably syphilitic, but the blood of the patients showed no complement deviation. The familial form of this condition is not common, so that the author felt justified in calling attention to this example. In another case in his practice three sisters were successively attacked. All showed the paranoid form. One sister has since died of tuberculosis. For years it has been noted that in familial psychoses paranoid forms are more common than others, while familial incidence naturally means hereditary taint. In discussion Delmes mentioned the case of the daughter of a celebrated professor developing evidences of hebephrenia now

many years ago. Last year a younger brother began to grimace and show negativism, suggesting incipient dementia precox. It is not unlikely that this case may become attenuated, but recrudescence will doubtless follow.

Cutaneous Filariasis in Guatemala.

According to a correspondent of *La Presse Médicale* for June 9, 1920, xxviii, 38, this very curious condition has been placed on record by Robles of Guatemala. It is an erysipelatous eruption of the face characterized by fever, burning and itching, and troubles of sight and hearing. Lemaire places the habitat of the disease as the western slope of the Cordilleras. The cutaneous lesions are the size of a pin head to a hen's egg with an average the size of a cherry or almond. The number varies from 3 to 5 and the lesions become cystic when they are found to contain filariæ of both sexes belonging to the genus *Oncocerca* and morphologically at least the species correspond to the *Oncocerca volvulus* of Leuckart which is widely diffused on the Congo. Brumpt, the South American parasitologist, prefers to call the species the *Oncocerca cæcutiens* because of its tendency to cause blindness. At present the condition is endemic only in Guatemala in a narrow strip of land running longitudinally. Thus far it has been encountered only at an altitude of 600 to 1200 meters. In one coffee plantation at 700 meters altitude every workman was a victim. At a slightly lower level there was not a case, although the workers went back and forth. Young and old are attacked impartially. Only field hands are attacked and the Indians somewhat more freely than the whites. From a map of the affected district the term "litoral" would seem to be a misnomer, for this region is at least 40 miles from the coast with which it runs parallel for about 100 miles. Some species of fly, probably a sandfly, is believed to carry the filaria.

Action of Uranium Salts on Neoplasms.

This form of activity does not seem to be exploited because of any relationship between uranium salts and those of radium, mesothorium, etc. It is only claimed that like selenium, neosine, trypan red, and other miscellaneous substances uranium salts are oncotropic, which seems quite different from the claim that their efficiency is due to radioactivity. Acqua, Almaglia, and others have worked along this line. The former studied the action of uranium salts on young vegetables and concluded that they inhibit caryocinesis. Almaglia then studied the action of a solution of uranium nitrate in very weak concentration (1-20,000) on adenocarcinoma induced in the tail of the white rat. Injections directly into these tumors showed no inhibitory effects. Vrzosek repeated these injections with more positive results and saw these tumors come to arrest and then regress after a series of injections. The frozen unstained sections under the microscope showed that the cells were stained yellow by the yellow oxide of uranium. Only the tumor, and not the tissue cells, was thus stained. It is even claimed that injections of nitrate of uranium stunt the entire growth of the young rats.

News of the Week.

Paris Fights Rats.—A plague of rats, developing from rodents that were hardy enough to make the journey from the trenches to Paris, where they multiplied in alarming numbers, has infested the French capitol. In the effort to rid the city of the pests every householder has been enlisted, and the sum of 300,000 francs has been voted by the Municipal Council for the work. For every dead rat presented at certain depots the Minister of Hygiene pays twenty-five centimes reward. Professional rat-catchers are using poison and poison gas in the war on the rodents, especially in market and slaughter-house areas. As a precautionary measure dust bins and refuse boxes are removed from the streets except within certain hours. Posters are distributed by the Ministry of Hygiene appealing to everyone to go rat hunting by day and night.

Red Cross Relief Program for the Coming Winter.—Appropriations amounting to $48,200,000 have been made for the American Red Cross relief program during the fiscal year ending July 1, 1920. Relief work in foreign lands will comprise nearly two-thirds of this, for it is believed that Central Europe faces another winter of famine, pestilence, and ruin. The recurrence of typhus fever on an unprecedented scale is anticipated.

Cholera in Corea.—Advices from Seoul, Corea, state that 9,000 cases of cholera have been reported, with 3,000. Opposition to cremation causes the natives to secrete the bodies of the cholera victims, which renders the control of the disease very difficult.

Second Rat-Poison Incident at Camp Dix.—For the second time rat poison has been discovered in flour at Camp Dix, presumably accidently upset in the flour. About forty members of the Motor Transport Corps were made suddenly and violently ill as the result of the last accident. Through prompt work on the part of the medical officers no fatalities or permanent ill effects occurred. The incident is being investigated.

Food Drafts for Germany.—Food drafts amounting to $8,000,000 and representing 800,000 ten-dollar food draft packages have been distributed in Germany since the American Relief Administration warehouse was opened in Hamburg, in addition to 50,000 fifty-dollar parcels by the Hoover organization.

Whiskey No Longer Medicine in the Navy.—The Bureau of Medicine and Surgery of the United States Navy has issued an order prohibiting the issue of spirituous liquors to naval vessels for medicinal purposes. When the stock on hand in medical supply depots is exhausted "no further purchases will be made and whiskey will be stricken from the supply table of the medical department of the navy." The use of ethyl alcohol is permissible when a medical officer deems alcoholic stimulation absolutely essential for the preservation of life.

Philadelphia Medical Schools Merge.—Plans have just been completed, after four years of negotiation, for the merging of the Medico-Chirurgical College and Hospital and the Philadel-

phia Polyclinic and College for Graduates in Medicine, forming the Graduate School of Medicine. The first regular course of the new institution will open October 4.

More Public Health Nurses Needed.—At the recent conference of State health officers held at Saratoga Springs, Dr. Josephine S. Baker, director of the division of Child Hygiene of the New York State Department of Health, made the statement that there are 9,500 public health nurses in the United States and places for 40,000 more.

Anterior Poliomyelitis in Boston and New York.—During the first half of the year seventeen cases of infantile spinal paralysis were reported in Boston, 16 cases during July, 94 cases in August, and 63 cases for the first nine days of September, according to advices from the Health Commissioner of that city to the Health Commissioner of New York City. There have been only 43 cases in New York, with three deaths, according to Commissioner Copeland, who has written a letter to every physician in the city requesting special vigilance and the reporting of all suspicious cases.

Malnutrition Class.—At Greenwich House, one of the United Neighborhood Houses of New York City, undernourished children just out of babyhood are being fed scientifically. The class at present is composed of seventeen little boys and girls, who are given a "supplementary breakfast," a nourishing luncheon, and a mid-afternoon meal of crackers and milk. After luncheon the children sleep for an hour and a half on the roof playground. Each of the children has shown a gratifying gain in weight. The malnutrition class is an outgrowth of the Baby Clinic held at Greenwich House every Thursday afternoon.

Crime Decreased by Prohibition?—According to Charles L. Chute, secretary of the New York State Prohibition Commission, there was a 34 per cent. decrease in the number of persons brought before the courts in seventeen of the larger cities in the State during the first three months of 1920 compared with the same period for 1919. There were arraigned 45,123 offenders of all ages during these three months of the present year, as against 68,535 last year, a decrease of 23,392. In practically all courts, he says, by far the greatest decrease has been in cases of public intoxication, disorderly conduct, and other offenses growing out of drink, although there has been a decrease in other offences as well. The reduction is attributed to prohibition.

Physical Test for Automobile Drivers.—The Health Commissioner of New York City has presented to the Secretary of State the suggestion that every person applying for a license to drive an automobile be compelled to give evidence of having good eyesight, good hearing, and good morals. Many licensed chauffeurs have defective eyesight and hearing, and many are said to be drug addicts. Out of 7,464 individuals registered as confessed drug addicts, according to the Commissioner, 534 were listed as drivers or chauffeurs.

Vital Statistics Encouraging.—During the first seven months of this year, according to figures prepared by the health authorities, New York City had a birth rate of 22.34, against 21.90 for the same period of 1919. The rate of infant mortality for last year was 83 in each 1,000, while the preceding year's rate was 92.

Lip Reading School Opened.—The New York City Board of Education has announced the reopening of the free school of lip reading for adults with defective hearing. The classes are held on Monday, Tuesday, and Wednesday evenings at Public Evening School 93. In addition to learning lip reading, hard of hearing women and girls wishing to learn a trade may join classes in dressmaking, millinery, embroidery, and cooking. Men and boys wishing to learn a trade should make application and state their preference.

Plans for Crippled Children.—Commissioner Bird S. Coler of the Department of Public Welfare, New York City, has announced that the five hundred or more victims of infantile paralysis will become resident patients in the city's hospitals. The transportation system is thus abolished. A public school teacher is provided for each hospital so that the education of the little cripples will not be neglected.

Insane Aliens to be Deported.—Officials of the Immigration Bureau at Washington are planning for the deportation of more than 1,700 insane aliens reported to the Bureau since 1915. The various states are said to have expended about $2,000,000 in the upkeep of the alien insane. More German immigrants are included in the 1,700 than from any other country.

The National Anesthesia Research Society, which will hold its first annual meeting in Pittsburgh, Pa., October 4-8, in conjunction with the Interstate Anesthetists Society, the Western Pennsylvania Odontological Society, and the Medical Society of the State of Pennsylvania. One of the special features of the session will be the awarding of prizes aggregating $200 for the best papers on original research in anesthesia presented to the society.

Charitable Bequests.—By the will of the late John J. Deery of New York City the following bequests were made: New York Catholic Protectory, $5,000; St. Vincent De Paul Society, $2,000; Church of St. Paul the Apostle, $1,000; Catholic Bureau for Dependent Children, on East Twenty-second Street, $2,000; St. Joseph's Day Nursery, 469 West Fifty-seventh Street, $500, and the Home for Crippled Children, at Port Jefferson, L. I., $1,500.

Civil Service Examinations.—The New York State Civil Service Commission announces examinations to be held October 2 for Medical Examiner and Assistant Medical Examiner, State Industrial Commission; Physiological Chemist, State Department of Health, and First Assistant Physician, Letchworth Village, Thiells, Rockland County. Applications should be made before September 25 to the State Civil Service Commission, Albany, N. Y.

The New York and New England Association of Railway Surgeons will hold its thirtieth annual session at the Hotel McAlpin, New York City, October 19, under the presidency of Dr. William B. Coley of New York. Clinics will be held at the Hospital for Ruptured and Crippled October 20, and at the Memorial Hospital and the Post-Graduate Hospital October 21.

Body of Miss Delano Arrives.—The body of Miss Jane A. Delano, who was Director of the Department of Nursing of the American Red Cross during the World War, arrived September 10 on the United States transport Sherman. A guard of honor from the Red Cross met the body at the army base, South Brooklyn, where the transport docked, and escorted it to Washington for burial. In the spring of 1919 Miss Delano broke down in France and died in the hospital at Savenay in April of that year.

Jefferson Medical College to Honor War Dead.—The Alumni Association of Jefferson Medical College, Philadelphia, on October 7, will dedicate a memorial to the graduates who lost their lives in service during the World War. The memorial is in the form of a bronze tablet, five feet high by four feet wide, on which will be engraved the names of the martyrs. Of the 1,147 graduates who entered the military service, twenty-five lost their lives.

Obituary Notes.—Dr. ROBERT H. HAMILL of Summit, N. J., died Sept. 5 in his sixty-sixth year. He was graduated from the University of Pennsylvania School of Medicine, Philadelphia, in 1878. He was a member of the American Medical Association.

Dr. STEPHEN V. W. STOUT of Jersey City, N. J., died Sept. 7 in the Memorial Hospital, New York City, where he had been under treatment for an affection of the throat. He was born in 1846, and was graduated from the College of Physicians and Surgeons, New York City, in 1868. Dr. Stout served as County Physician of Hudson County, N. J., from 1873 to 1876, and as member of the New Jersey Assembly in 1898.

Dr. ALBERT E. KOONZ of New York City died Sept. 8 at St. Luke's Hospital, after an illness of six weeks. He was forty-seven years old. He was graduated from the College of Physicians and Surgeons in 1896. He was also a graduate in dentistry.

Dr. FREDERICK HENRY GERRISH of Portland, Me., died Sept. 8 at the age of sixty-five. He was graduated from the Medical School of Maine in 1869, specializing in surgery. He held a professorship in the University of Michigan until 1873, when he became a member of the staff of Bowdoin College, of which institution he was emeritus professor of surgery at the time of his death. He was a former president of the American Academy of Medicine and of the American Therapeutic Society.

Dr. HARMON NORTHROP MORSE, professor of chemistry and director of the chemical laboratory at Johns Hopkins University, died at his summer home at Chebeague Island Sept. 8, at the age of seventy-two. He had been on the staff of Johns Hopkins since 1876.

Dr. GEORGE H. MCGUIRE of the Bronx, New York, met death September 12 when the automobile in which he and seven members of his family were riding plunged twenty-two feet off an elevated road at Dobbs Ferry, N. Y. All but one, the physician's twelve-year-old son, of the eight were killed, probably instantly. Dr. McGuire was born in 1862, and was graduated from New York University Medical College in 1883.

Correspondence.

REPORTING PROGRESS RELATING TO IMPROVING THE MILK AND BUTTER SUPPLIES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It is interesting to realize how many matters of a scientific nature have more or less relevancy to the "Great Milk Question." I have lately had an inquiry from Kansas City relating to the present status of the movement with which it is now somewhat widely known I am interested. My latest communication to the MEDICAL RECORD relating to the causative effect of diet in so-called rheumatism, seems to have excited considerable interest if I am to judge by the communications sent to me relating to that matter.

As a matter of fact I may say that I have unwittingly become the repository of a large amount of suggestive information from various sources, a consideration of which has led me to rearrange my conclusions previously formed, which may be of general interest, and which have a bearing on the character of the milk and butter supplies. I have also vicariously undergone some self-inflicted experimentations that have strengthened my views to the effect that the milk and butter supplies produced and sold today are not harmonious in character with our latest acquired scientific general knowledge.

From the sources of information received there seems to be little doubt that there may be directly and indirectly acting, irritative conditions of the blood, varying in character, that will, in connection with various other special conditions, produce one or other of a number of diseases, and stand as obstacles to cure. It seems likely that such irritative conditions of the blood may be hyperacidity, excess of sugar, too much concentration of well balanced nutrients, lack of balance in the nutritive constitutients, deficiency in the nutritive supply, high blood pressure, too low blood pressure, too much protein, absorbed protein split-poisons, unexcreted accumulation of normal metabolic products, and, not to be forgotten, accumulation of putrefactive poisons.

These putrefactive poisons, as well as split-protein poisons, are more or less present in all market milk and butter products sold today; and practically nothing is being done to eliminate the menace of such contaminants in those vitally important foods, outside of ordinary pasteurization. It seems clear that one or a combination of such blood irritants may be present in the blood and be a causative factor in producing rheumatic arthritis, gout, lumbago, diabetes, various skin affections, cancer, exophthalmic goiter, nephritis, and other troubles.

Accepting such conclusion as a probability, it is obviously a matter of importance that both milk and butter should be as free as possible from such damaging matters, prior to their consumption. It is really a sad fact that no milk or butter attainable by the general consumer is as yet as good as it should be, and that under present conditions of handling those products no one can know the relative character of what is consumed. There is no

way of improving this situation, so far as is known, unless *all* milk and butter supplies are so treated as to remove the menace. The treatment required is relatively simple; and after the cost of installing the means for treating them, the increase in cost is very slight. In fact, so far as the better grades are concerned, the cost of production is considerably lessened.

There is no hope of securing the desirable change of treatment without *forcing* dealers to do what at least some of them now know it is their duty to do; and it will require a considerably large new moneyed investment for new equipment, and an education of consumers to understand the situation. Now inasmuch as milk dealers are not in business for their health's sake alone, naturally no one is willing to undertake the new methods unless he can be protected against loss in their undertaking.

Realizing the need of overcoming that situation, I make the basis of my reform proposition, the principle that has been entirely overlooked hitherto in reform work, viz., controlling the various methods and means for accomplishing the result by patenting the same so as to be able to place the protecting patents into the hands of selected distributors, who through the held monopoly would be able to do the needed educational work among consumers, and eventually secure the cooperation of other dealers by consolidation with them, thus cutting down cost of distribution.

After thirty-five years' experimental work I have found that it will require the issue of about twenty-six patents to secure the protective power. About half of the applications filed have been granted, and good progress is being made with the balance. It is now up to me to secure the funds needed by a holding company to work the patents, and to carry the campaign into effect. I am putting this matter up to about one hundred of the most prominent men and women of the country whose backing will be strongly moral as well as financial in connection with the work.

I don't know that I shall live to see this movement carried out, as the "three score years and ten" age has been passed; but my general health is good and I am struggling hard to prolong my life. I eat as lightly as I can of a regulated diet as to which I will write later on. I have evolved a "bran cake," and a method of preparing oats, that are worthy of adoption generally.

I want the openly published approval of all medical men and scientists whose approval will be helpful, and will be glad to undertake the education that apparently all need as to the advance that it is now clear I have made. It has taken me eight years to realize that I have gone ahead of everybody else in this matter; but that realization has been forced on me by the circumstances of the struggle, and I beg medical confrères in particular not to think my head has been swollen in this connection. My thoughts have been far too much taken up by a not as yet completely resolved arthritis of the knee for three years to feel any great degree of self-pride as to anything I have done in my nearly ended life.

EAST ORANGE, N. J.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 20, 1920.

Face Surgery.—A somewhat remarkable book dealing with plastic surgery of the face has been written recently by Major H. D. Gillies, F. R. C. S., and published by Frowde, and Hodder and Stoughton. Major Gillies was in charge of the hospital at Fragnal, Sidcup, near London, which was brought into being during the war for the purpose of treating facial injuries which, under the conditions of warfare that prevailed, were fairly common. It goes without saying that a great deal of the surgery appropriate to the cases had to be learned and therefore some originality was brought into play and much skill and ingenuity exercised. Indeed, the book is a record not of brilliant surgery alone, but of the physical and esthetic salvation of men who had been changed, by injury, at most out of the likeness of a human being. It was an effort of humanity on a wide scale as well as an exhibition of surgical skill in its highest phase. The photographs with which the pages of the book are profusely illustrated show all the stages of the reconstructive work and prove that few cases are so desperate that facial surgery cannot better them and that in many instances seeming miracles have been performed. Sir Arbuthnot Lane, who has written a preface to the volume, points out that the value and importance of plastic surgery have not diminished with the close of the war and insists that "ugly scars resulting from burns and accidents, deformities of the nose and lips, harelips and cleft-palate, abnormal protrusion or ill-development of the mandible, moles, port-wine stains, all abound and are not only the constant source of the greatest distress and anguish, but naturally lower the market value of the individual." The book covers in a very satisfactory way the entire subject and in it are included chapters on the principles and underlying plastic surgery by Captain Fry and the administration of anesthetics by Captain Wade. The author is known in some of the big cities of America as in the autumn of last year he visited the United States and gave several addresses on plastic surgery.

The Census of Next Year.—In April next the census will be taken in Great Britain. One of the features of the new census bill, which will come into force shortly, gives the power to hold a census every five years instead of as formerly, every ten years. The Minister of Health has a wider field than that concerned with health functions proper. He deals with industrial matters, occupation and employment, questions of the greatest value to actuaries and life insurance companies, as well as to those concerned with matters of housing. There are three census authorities, one for England and Wales, another for Scotland, and another for Ireland. Under the bill it is proposed to leave out the "fertility" inquiry, the number of children born and alive in the case of existing marriages. That inquiry which was made in 1911 was of importance as bearing upon the tendency of a diminishing population, but owing to the war the results have not been completely published. It is a question which need

not be repeated on the next occasion. No inquiries will be made about infirmities, but in their place it is hoped to substitute inquiries as to occupation, industries, education, continuation schools, transport, housing, and old-age pensions. A knowledge of the extent of the stream of traffic between places of employment and residence would be of great importance, inasmuch as it would be of the highest value in regard to matters like housing, overcrowding, and transport. No questions will be asked about religion, military service or illegitimacy. Every census has brought its new problems. At the last census the important inquiry was concerning the fertility problems. Economic labor questions are now regarded as of more importance.

Protests Against Health "Inquisition."—There is no doubt that the new Ministry of Health has a hard road to hoe. The English Catholics are now up in arms against what they term attacks on the moral law and the infringement of individual liberty by the socalled "inquisition" which it is proposed to establish under the Ministry of Health. A meeting of protest was held during the session of the National Catholic Congress held recently in Liverpool. A letter was read from Mr. Hilaire Belloc in which he expressed the general sentiments of the Catholic with respect to the proposed measure. He pointed out that they knew what State control, as it is called, produced; what were its effects upon the individual, the unit and the family; its irresponsibility, the impotence of the voting masses to direct or even check it, and the singular power exercised over it by the few rich men who controlled the political machine. Catholics had a definite and unalterable view of how human life should be lived and of what was tolerable and what intolerable in the action of the State upon the individual conscience and the family. Resistance to the most immoral and monstrous of the new devices which the Ministry of Health was certain to attempt would be met officially by an angry intolerance. There would be no opportunity for compromise. The powers of the Ministry of Health would be under the double control of great capitalists and extreme theorists and they would be used to impose things to which no Catholic could submit. They could not admit an interference with the liberty of marriage in adult men and women, nor any element at all of the horror known as eugenics. They could not admit what was called sex teaching, or any one of the whole series of propositions regarding sex hygiene; neither could they admit the claim of the State over the children as against the claim of the parents. Religious resistance, the writer went on to say, might well be fruitful, because the politician was easily frightened, and knew in his heart that these new extensions of irresponsible power had no popular backing. The politician was, as a rule, a weak bombastic man who had taken up a Parliamentary profession either for a salary, the limelight, opportunities for picking, or the power of patronage. Cardinal Bourne made a speech at the Congress in similar strain and appealed to labor to fight against infringement of individual liberty. A resolution was passed declaring that the Ministry of Health was of a character to justify corporate action. It is obvious that the Catholics intend to fight any interference with the powers of the church and this resolution may seriously embarrass efforts made by the Ministry of Health to improve the health of the country, if such efforts clash with the views of Catholics or their directors.

High Birth Rate Maintained.—The quarterly return of births, marriages and deaths shows that during the June quarter of this year nearly 6,000 more boys than girls were born in England and Wales. The figures also disclose the facts that the births registered during the three months ended June 30 numbered 248,665 and the deaths 119,283. The number of persons married during the three months ended March 31 was 138,302. The number of persons married during the first quarter of 1920 showed a decrease of 64,000 from the number in the preceding quarter, but was 18,026 more than that in the first quarter of 1919; it corresponds to an annual rate of 1,418 per 1,000 total population, including armed forces at home and abroad in 1919. The births registered in the second quarter of 1920 were 22,417 fewer than in the preceding quarter, but 99,841 more than in the second quarter of 1919; it was the highest number recorded in any second quarter since the establishment of civil registration. Of the 245,665 births, 12,132 or 2,201 more than the number in the corresponding quarter of 1919, were illegitimate. The births of males numbered 127,258, and those of females 121,407. Male births were in proportion to female births as 1,048 to 6,000, the average proportion in the ten preceding second quarters being 1,040. The 245,665 births registered during the quarter correspond to an annual rate of 26.6 per 1,000 total population, including armed forces at home and abroad in 1919. The natural increase of population in England and Wales last quarter by excess of births over deaths was 129,382, against 45,701, 51,650 and 40,364 in the second quarters of 1917, 1918, and 1919. The deaths registered in England and Wales last quarter were 18,354 fewer than in the preceding quarter, but 10,823 more than in the second quarter of 1919. The 119,283 registered deaths included 62,025 of males and 57,255 of females. The total deaths correspond to an annual rate of 13.0 per 1,000 total population in England and Wales in 1919. Influenza was stated to be either a primary or contributory cause of death in 4,370 or 3.7 per cent. of the total deaths registered last quarter. Infant mortality, measured by the proportion of deaths under one year of age to registered births was equal to 82 per 1,000, being 6 per 1,000 below the average in the ten preceding second quarters.

3. Acute Intestinal Obstruction: A Study of a Second Series of Cases from the Massachusetts General Hospital.—Edward P. Richardson reports a series of 118 cases in 115 individuals, in direct continuation of the first series, reported by Scudder (*Northwestern Medicine*, October 1908), the present series including the ten years from 1908 through 1917. There was a general mortality of 41.5 per cent. in 118 cases operated upon in the second series, as compared with a previous mortality of 60 per cent. From a comparison of the results of the two series of cases the writer concludes that the period during the second ten years shows a slight but definite advance in the treatment of this condition. In spite of this, the results of operative treatment remain far from satisfactory. Nor is there suggested, from the study of these cases, or from the experimental evidence, any radical means of improving the results. From the nature of the condition, the results of treatment of late intestinal obstruction are likely to remain bad, in the absence of revolutionary advances in surgical knowledge. The important field for improvement in results lies in earlier diagnosis and early operation, at a stage when so difficult a problem for surgical treatment is not presented. An average duration of time from the onset of symptoms to operation of approximately three days cannot be considered satisfactory, and the chief hope for better results lies in the reduction of this period.

1. The Use of Arsphenamin in Nonsyphilitic Diseases.—Reasoner and Nichols discuss briefly the various nonsyphilitic diseases in which arsphenamin has been found beneficial, and summarize their observations as follows: For practical therapeutic purposes, the beneficial effects of arsphenamin and neo-arsphenamin are most apparent in a limited number of spirochetal diseases. They act as specific in Vincent's angina, relapsing fevers, yaws, gangosa and pulmonary spirochetosis (if given early) in man, and in equine influenza. A therapeutic effect is noted in rat-bite disease, in certain dental conditions and in fowl spirochetosis. The complete measure of the effect in the latter condition has not yet been established. No apparent benefit has been found in such other spirochetal diseases as Weil's disease and yellow fever. Good results have been obtained in syphilitics, in a number of nonsyphilitic conditions, which are influenced adversely by that disease. Their use has been recommended in conditions in which arsenic is indicated. In such case the effect is alterative rather than specific, and ordinarily there is no special advantage over liquor potassii arsenitis. There is a limited effect on certain protozoal diseases, as malaria (tertian and quotidian), some of the trypanosomiases and leishmaniasis. It is possible, however, that this effect may be nonspecific. With the exception of anthrax, and possibly glanders, few favorable results are reported in bacterial diseases. Except in Vincent's angina, arsphenamin and neo-arsphenamin should be administered intravenously in medium-sized dosage. Two or three injections usually accomplish the desired purpose, except in pulmonary spirochetosis, which may require a series of injections. In diseases showing liver involvement, it has been recommended that neo-arsphenamin be given on account of its supposed lesser degree of toxicity.

4. Some Observations on the Treatment of Gonorrhea with Detoxicated Vaccine.—Corbett and Osmond detail briefly a series of cases treated with detoxicated vaccine with the object of judging its effect upon them both clinically and serologically. A series of "controls" received no vaccine. All cases were admitted to the hospital suffering with acute gonorrhea and with gonococci present in urethral smears were placed in either the "test" or the "control" series. All cases were treated on the same general lines, smears were taken on average once a week, and urines were examined twice weekly. The 123 "test" cases received detoxicated vaccine commencing on the day of admission. The first 18 of these received a total of 40,000 millions spread over a period of 30 days, but this was later given up and the remaining 105 received a total of 60,000 millions within the same length of time. The vaccine was given subcutaneously alternately into either arm. In view of the fact that cases were taken serially and not picked, and that test cases and controls were treated on exactly parallel lines, and that all were submitted to a long period of observation, it is considered noteworthy that the average duration of the disease in test cases was 38.5 days as compared with 48.4 days of controls—a decrease of nearly 10 days per case.

5. Herpes and Chicken-pox.—Claude E. Ker, discussing the debated question of the alleged relationship of herpes and chicken-pox, says the coincidences of occurrence are getting sufficiently numerous to be somewhat puzzling, warranting a review of the whole subject, which he proceeds to give. He discusses the cases of relationship under (1) cases of herpes zoster followed by chicken-pox; (2) cases of chicken-pox followed by herpes; (3) cases of herpes and chicken-pox in the same individual at the same time; (4) cases of chicken-pox and herpes appearing simultaneously in different individuals. It is also noted that there is some evidence that herpes occasionally appears in what might be described as an epidemic form. The difficulties in accepting the theory of the identity of the virus of herpes and chicken-pox are cited. Admitting that it is easy to exclude absolutely the possibility of a real relationship between the two conditions, much yet remains to be explained. The question of immunity, for instance, requires careful consideration. Many patients who suffer from herpes have undoubtedly had chicken-pox previously, and there is no reason to believe that herpes

confers any protection against chicken-pox. Is it to be assumed that the general blood infection is not sufficient to make the individual immune to the local nerve infection and vice versa? Moreover, herpes does not protect against itself, second attacks being known to occur. As second attacks appear to be rare, the mere fact of their existence is no real argument, as some have proposed, against the infectivity of herpes, as they occur occasionally in all the infectious diseases. But from another point of view, herpes does not behave as if it depended on a living virus. The frequency with which it has been reported to appear during a course of treatment with arsenic is very difficult to explain on any theory of infection. The key to the mystery lies in the hands of the general practitioner. All cases in which the association of the two diseases is noticed should be carefully noted and put on record. It is equally important to keep a note of all cases of herpes which, occurring in a family where there are susceptible children, are *not* followed by chicken-pox. The possibility of a missed case of chicken-pox being the real cause can never be entirely excluded, especially when one remembers that the whole eruption of that disease may be represented by one spot and in consequence is very easily overlooked. A series of similar observations, however, would give some idea of what percentage of cases of herpes are followed by chicken-pox, and should such a percentage be found considerable the relationship between the two conditions might be more reasonably accepted. The proportions, moreover, of herpes patients who have or have not previously suffered from chicken-pox would be an interesting addition to one's knowledge. Attention might also be given to the question of second attacks of herpes and to the dates on which herpes occurred in the practice of the observer and his neighbors with a view to investigating epidemicity. Until a considerable mass of information can be obtained the question must be left an open one, recognizing at the same time that such information is necessary before one can, with any justice, absolutely repudiate the theory of identity.

8. Discussion on the Treatment of Denervated Muscle and on the "Disuse" Theory. Introduced by J. N. Langley.

7. Dietetic Deficiency and Endocrine Activity, with Special Reference to Deficiency Edemas.—Robert McCarrison states that the fact that the endocrine organs are profoundly influenced by dietetic defects has been demonstrated by experimentation on pigeons, guinea-pigs, and monkeys. Animals of these species were fed on six classes of deficient dietaries. The first was deficient in all three classes of vitamines and in suitable protein, and was disproportionately rich in carbohydrates; the second was deficient in B and C vitamines and disproportionately rich in carbohydrates and fats; the third was deficient in B-vitamine and disproportionately rich in carbohydrates and fats; the fourth was deficient in A and B vitamines; the fifth in B-vitamine only; the sixth in C-vitamine only. The effects of these dietaries on the endocrine organs are attributable to three factors operating in varying combinations: (1) deficiency in vitamines; (2) imperfect balance of the food with respect to proximate principles; (3) the fortuitous occurrence of pathogenic agents in the body. From a study of the different endocrine glands in accordance with these premises the writer draws the following summary: (1) Dietetic deficiency has a profound influence on endocrine activity. (2) All endocrine organs, with the exception of the adrenal glands and the pituitary body, undergo greater or lesser degrees of atrophy and depreciation of functional capacity as a result of dietetic deficiencies. (3) The adrenal glands, and in males the pituitary body, enlarge in consequence of dietetic defects; the former greatly, the latter slightly. (4) The adrenal glands are, of all endocrine structures, the most susceptible to dietetic defects. (5) The character of the adrenal enlargement varies with the character of the dietetic deficiency. (6) The adrenalin content of the enlarged adrenals varies with the character of the dietetic defect; it is in excess of normal when the food is deficient in vitamines, in proteins, and disproportionately right in starch; it is below normal when the diet is scorbutic, and also when concurrent infections are associated with dietetic defects. (7) Edema is invariably associated with massive enlargement of the adrenal glands in pigeons fed on autoclaved rice. But massive enlargement of the adrenals is not invariably associated with edema. This association bears some intimate relationship to the adrenalin content of the enlarged organs; when the content is high edema occurs in 86 per cent. of cases, when the content is low edema does not occur. (8) Fresh butter contains some substance which tends to protect against edema. This substance was not present in cocoanut oil. (9) The hypothetical "anti-edema" substance in butter has a pronounced influence over the adrenal glands. It appears to exert its protective action against edema by maintaining their adrenalin content at a low level. (10) Butter varies in its capacity to protect against edema. This variation is dependent on the quality of the cow's food: butter is richer in "anti-edema" substance when the cows are fed on green fodder than when they are fed on dry fodder. The writer concludes that these observations have a significant bearing on the causation of deficiency edemas in the human subject.

1. Uterine Fibroids Complicating Pregnancy. A. P. Heineck.
2. Case of Gundu Observed in Bahia, Brazil. F. Luz and O. Torres. (Translated by A. McShane.)
3. Dressing for Fracture of the Clavicle. E. L. Leckert.

1. Uterine Fibroids Complicating Pregnancy.—A. P. Heineck bases his discussion of this subject on personal experience supplemented and controlled by an analytical survey of 380 cases reported with adequate data, in which the diagnosis received either operative or post-mortem confirmation. From this study he makes, among others, the following observations: Uterine fibroids are found associated with any form of pregnancy and occur in gravid uteri, otherwise normal or abnormal, congenitally so or acquired. Uterine fibromyomata exert an unfavorable influence upon conception, gestation, labor, and the puerperium. Uterine fibroids originate and may continue during all periods of menstrual life, may first become manifest in primiparae, deutiparae, and multiparae. By virtue of their weight, volume, or location, they displace and fix the pregnant uterus forward, laterally, upward, downward or backward, causing pathological versions and flexions, and even pelvic impaction and incarceration. When pregnancy develops in a myomatus uterus, the nutrition of the fibroids is unfavorably influenced by the altered conditions, and hypertrophy of the tumor results. Fibroids, like other tissue masses, are subject to inflammatory and degenerative changes. These changes occur previous to, or after abortion, or prenature labor; previous to or after full-term labor. Inflammation of a fibroid terminates in gangrene, partial or complete, central or peripheral; in suppuration. or in the formation of adhesions. Adhesions of inflammatory origin, by displacing and fixing the gravid uterus, interfere with its functions and that of contiguous viscera, and are an important factor in the etiology of dystocia. Fibroids are subject to calcification, to fatty, cystic, myxomatous, or red degeneration. Red degeneration, which is an aseptic necrobiotic process characterized by hemolysis and autolysis of tissues, is occasionally met with in non-gravid myomatous uteri, but is more frequent, and more intensive in uterine fibroids co-existing with or complicating pregnancy. During its entire course, uterine fibroids are a grave menace to preg-

nancy. Treatment is most successful when it fulfils the following conditions: (1) The delivery of a living and viable child; (2) the complete removal of all fibromyxomatous tissues; (3) the restoration of the mother to sexual and anatomical integrity. Expectant treatment has its dangers,—postponement of the climacteric to fifty odd years; formation of submucous nodules, causing repeated hemorrhages; cardiac degeneration; thrombosis and embolism; malignant degeneration of tumor tissue. Fibroid tumors of the uterus are amenable to operative removal, and the tolerance of the gravid uterus to operative procedure is well known. The imperative indications for surgical interference are given and the different procedures discussed.

1. Puerperal Eclampsia in Hospital Practice. Robert E. Coughlin.
2. Suprapubic Prostatectomy by the Two-Stage Method. J. Sturdevant Read.

1. Puerperal Eclampsia in Hospital Practice.—Robert E. Coughlin makes the following statements: (1) That there is no expectant treatment in a consideration of puerperal eclampsia. (2) That early control of the convulsions and emptying of the uterus will bring about the best results. (3) That veratrum viride is a very important drug in the treatment of convulsions due to the toxemias of pregnancy. It acts best when given in large doses at frequent intervals. It may be administered either by hypodermic injection or by mouth, but the former method is preferable because of a better and more prompt action. It should be given until its physiological action,—slowing of the pulse,—is produced. (4) That atrophine sulphate should be tried in desperate cases, especially where there is a tendency to pulmonary edema. (5) That while careful nursing, hot packs, applications to kidney region, and diet, are important, the prime indication for treatment is the control of the convulsions and early evacuation of the uterus, thus bringing about improvement in the metabolism, improvement in the circulation by reducing blood pressure, improvement in the condition of the urine, improvement in the temperature, pulse and respiration, saving the heart and cardiac muscle from unnecessary strain,—in a word, the bringing about of metabolic changes so that the balance between absorption and elimination has been increased in favor of elimination.

Glycuronuria.—The present number contains two articles on this subject, by Sabatini and Lorenzani respectively. The conclusions of the former are that the finds to date are incomplete and conflicting, but they have promise for the future if well tested. To this end we must have readily applicable tests which do not necessitate a large quantity of urine and which are specific for glycuronic acid. A single test should be decisive. The best for the purpose are the napthoresorcine test of Tollens and Rorive and the alphanapthol test of Goldschmiedt (with or without modifications by subsequent chemists) the former being given the preference. The author however believes that the Goldschmiedt test is the more sensitive, the more rapid, etc., even if not actually specific. In about ten per cent. of cases the two reactions disagree. The alpharesorcin and socalled diphenylamine reactions appear to agree in all cases tested. In the author's experience the ingestion of nitrates does not affect the naphthoresorcine test but powerfully modifies the alphanaphthol and diphenylamine tests. Lorenzani concludes that it has not been proved that glycuronic acid when present in excess in the urine—as in diabetes—is due to the inability of the organism to oxidize carbohydrates. It is more probable that excess of this substance is an indication of an accumulation of toxic material in the blood. Attempts to base a prognosis on the urinary content of glycuronic acid are hazardous because of unusual finds—thus the author once found an increase in a case of pancreatic cancer which occluded the choledochus.

June 21, 1920, xxvii, 25.

Dissimilarities Between Lethargic Encephalitis and Dubini's Disease.—Ronchetti arrives at certain conclusions with special reference to the identity of the myoclonic form of sleeping sickness with the Dubini or as he terms it Dubini-De Vecchi disease—electric chorea. In both syndromes, the ancient and modern, the mortality was high and especially in the older episode; Frua reports two recoveries from the Dubini disease to illustrate the rarity of recovery; and the mortality in general ranged from 80 to 90 per cent. Although Dubini's syndrome was styled a chorea, paralysis was very common and it was alleged to be present in over three-fourths of all cases. The absence of eye symptoms in Dubini's reports has been used to discount the identity of the two affections but Pignacca, a contemporary, speaks of fixation of the eyes and strabismus. Ptosis as such is not mentioned. Dubini does not speak of lethargy but as it were goes out of his way to emphasize the intelligent and wide awake behavior of the patient. It is true that in one case he mentions lethargy but in this subject there was found at autopsy a focus of softening in the thalamic region. Pignacca goes a little further and mentions a terminal lethargy comparable with the stupor of typhoid fever. He also mentions the great frequency of convlusive attacks; of 36 subjects 25 showed epileptiform convulsions and therefore Frua proposed the name of "convulsive typhus" for the affection.

1. A Case of Endothelioma of the Brain. Max A. Bahr.
2. Medical Legislation Needed. P. A. Zaring.
3. Bilateral Lobar Pneumonia with Empyema. Edward Binzer.

2. Medical Legislation Needed.—P. A. Zaring emphasizes the following points: When the honest man has taken all the prescribed courses of learning, finally graduating in an "A Grade" medical college, he should be permitted to practise medicine without having to chance the State Board. And no one should be permitted to practise medicine without a diploma from such a college. Every county with a small number of physicians, say fifty or less, should have a physicians' institute. Where there are larger numbers of physicians the counties should be divided into districts. Two or more small counties, or parts of counties, might be combined into one district, to augment the interest. Each institute should meet regularly, say once a month, and every member should be required to attend a certain per cent. of all meetings. He should be paid something for such attendance, and fined for non-attendance of the required number of meetings. Because physicians actually must render service without any possible chance to secure bills in advance, therefore they should have special provisions for collecting physicians' bills. No property belonging to the family should be exempted by law. A garnishee law should obtain in these cases.

The Asthenia of Epidemic Encephalitis and of Grippe.—Litvak writes briefly of this subejct. One of the points of similarity between the two affections is the asthenia. In the spring of 1918 the author saw the début of the pandemic at Bologna, Italy. He was struck with the following peculiarities: the fever was not usually preceded by chills, the headache and vomiting were not always associated with alimentary errors, and the rachialgia and malaise were associated with an inexplicable asthenia which bore no relation to the severity or duration of the brief and usually mild affection. This asthenia was sometimes initial, sometimes intercurrent and often appeared for the first time during convalescence. Neurasthenia was often a sequel. Asthenia of influenzal origin, postinfluenzal neurasthenia—these are described magistrally by Gowers, Strümpell and Oppenheim and nothing further need be said on this subject. Passing to epidemic en-

cephalitis we find asthenia present here although masked by the somnolence and other cerebral symptoms. But why may not somnolence be in itself a manifestation of primary asthenia? The prevalent opinion which makes of somnolence a regional manifestation due to the implication of the hypnic zone in the base of the brain has been antagonized—for example by Zagari of Modena, who attributes the somnolence to depression and not to irritation of certain zones which preside over sleep. In addition to mere somnolence there is marked depression of all the psychic functions. It is admitted that the mesencephalon is primarily attacked by the toxic products of the disease, which explains the incidence of somnolence in these cases. But how explain the cases in which insomnia, agitation and delirium are substituted for somnolence? This should not be difficult, for this dualism is seen throughout the whole of pathology. The author cites certain sequelæ in grippe cases in which the syndromes—erethetic or torpid—appeared after some weeks and ended fatally from organic disease.

Practical Significance of Stercobiline.—Brule and Garban state that the substance stercobiline is simply fecal urobiline. The generally accepted view to-day is that the entire quantity of stercobiline is derived from the true bile pigments (bilirubine) in the intestine. These reach the intestine through the choledochus and are transformed into stercobiline and stercobilinogen. Bilirubine is absent from the stools save in the new born. In other words it is completely transformed somewhere in the course of the intestine into the two substances mentioned. It is evident that the amount of stercobiline in the feces is an index of the amount of bilirubin and bile which enters the intestine. This may be obtained by chemical or spectroscopic analysis but the results are only approximate. It is very difficult to extract all of the stercobiline from the feces. Attempts to oxidize the stercobiline into the companion pigment have not been successful in practice. But the two pigments are very unstable and have been transformed into a third substance which has been termed bilirubidine. *In vitro* however this change is very slowly accomplished. Another pigment has been found in animal feces known as bilicyanine which is nearly related to biliverdine. Nothing has thus far been said of the absorption of stercobiline or rather bilirubine in the intestine and its elimination by the uring as urobiline. The latter is not of course a constant constituent of the urine while it may also reach the latter from sources other than intestinal absorption. The problem of quantitatively estimating the amount of bilirubine which enters the intestine is very complex. Only in fistula cases is there a special opportunity for the investigation of these matters. The author would therefore seek to determine the amount of bile secreted rather by a study of the amount of biliary acids in the feces.

La Presse Médicale.

June 30, 1920, xxviii, 44.

Oscillometry in Asthenics and Maniacs.—Benon and Leinberger contribute a brief article on this subject. In asthenia we see a psychoneurotic state characterized by amyasthenia and anideation; or in other words the muscular system is weak in comparison with the vegetative functions, while the mental processes suffer in the same fashion, being unable to function in respect to ideation, recollection, etc. This syndrome is complicated not rarely by deliriant manifestations. The opposite condition to this is mania with its increase of muscular force and of ideation. In these two opposed states the behavior of the heart should show marked differences and these the author has attempted to elicit through the use of the oscillometre. If in the normal subject the amplitude be represented by 2 to 2½ it is found to be in mania as high as 6; while in asthenia it is chiefly less than 1 degree—about 2/3 of one degree to a full degree. The differences between the maximum and minimum blood pressures are seen to be about 9 in. the maniac and 2 to 2½ in the asthenic. There is here seen in operation a rule—the amplitude of the maxima is directly proportional to the amplitude of the pulse. In other words in the asthenic the oscillometric index as well as the differential pressure is slight, while in the maniac they are marked. Thus far the authors have found no exceptions to these finds, which can only mean that the force of the heart differs radically in the two conditions.

La Bulletin Médical.

June 19, 1920, xxxiv, 32.

Mongolism.—Apert analyzes this condition from the anthropological standpoint. Is it an illusional resemblance or are these children throwbacks to Mongolian ancestors? The chief analogy is the eye both in the obliquely directed palpebral fissures and the epicanthus. The resemblance is apparent to the laity and the author cites examples: one child bore the nickname "Oyama." In another case the nurse who was wheeling a "Mongolian" baby was repeatedly asked if it were a Chinese and in a third there was evidently a suspicion of illegitimacy or of a changeling. But even in cases without the oblique eyeslits and the epicanthus there is something Mongoloid about these children which arrests the beholder. The head shape for example is markedly brachycephalous, the nose and cheek bones and general harmonics of the face are Asiatic. Even over and above these similarities there is a something intangible which calls up imperfect memories of having seen such features—those of actual Mongols either in life or art—before. In Mongolian idiots we usually find so many stigmata of degeneration that the somatic peculiarities above described naturally range themselves under the same head. The so-called blue sacral Mongolian spots, strange to say, have never been seen in Mongolian idiots but the few recorded cases in whites have been seen in normal children. Thus far we know nothing of the causes of Mongolism. The author does not allude to the occasional occurrence of Mongolian features in normal white subjects: in one case known to the reviewer the father (or perhaps grandfather) of the young woman in question had been a missionary in the Orient before her birth. Under the head of treatment the author refers to pluriglandular extracts—thyroid-suprarenal—combined with mineral matter—manganese and calcium—which seemed to cause considerable initial improvement but later became inert.

Acidosis in Acute Abdomen.—Labbé speaks of the increasing importance of the study of acidosis in both medical and surgical pathology. We now look systematically for diaceturia and acetonuria. Infrequent as a general condition, it is relatively common in acute abdomen and notably in appendicitis and cholelithiasis. Here acidosis varies directly with the intensity of the operation, disappears with the vanishing phlogosis, and reappears with relapse. It may be shown that it is not due to fasting nor to chloroform when given for operation. It is now believed to indicate implication of the hepatic function and should be seen in association with urobilinuria, ammonuria, and aminoaciduria. In fact, acidosis stands in some relation with the pathology of organs drained by the portal vein.—*Gazette des Hôpitaux.*

Cholemic Hemorrhages.—This term is applied by Petren to certain fatal post-operative bleedings of which he has collected a series of fifty-eight Swedish cases. The subjects of operation have at the time some form of jaundice, and any mild intervention such as trial laparotomy may end fatally. Naturally, operations on the biliary passages are the most common source of this accident. It is necessary that the icterus shall have been present for several weeks, and as a rule the condition is manifest as a hematoma on the first or second day after intervention. In other cases the blood is effused into some cavity or passage. One lesson is evidently not to delay operation when a subject develops jaundice.—*Schweizerische medizinische Wochenschrift.*

Book Reviews.

ATLAS OF OPERATIVE GYNÆCOLOGY. By BARTON COOKE HIRST, M.D., Professor of Obstetrics, University of Pennsylvania. Quarto of 292 pages, with 164 plates and 46 figures. Philadelphia and London: J. B. Lippincott Company.

IN this book Hirst says he has attempted the graphic method of describing operations for conditions peculiar to women by a series of colored illustrations showing the separate steps of each operative procedure. Most of the illustrations were made by Mrs. P. P. Chase after repeated observation of the performance of the operations. The text has been subordinated to the illustrations, thus saving the readers time.

The illustrations show such operations as the author has found most useful and give the technique which he employs. This is an advantage in one way, since it gives the selection from the almost innumerable methods in gynecological surgery which an author and operator of wide experience considers best; but, on the contrary, there are many excellent methods which other operators of equally wide experience might prefer but which are neither illustrated nor described in this book, therefore it is not nor does it pretend to be complete.

Before taking up the individual gynecological operations, about 30 pages are devoted to the subjects of equipment and preparation for gynecological operations, closure of abdominal wounds and operative technique. The author's method of opening the abdominal cavity not only is, as he says, "troublesome to nurses and no doubt to the patient," but also appears to the reviewer, who has himself had a rather extensive experience in abdominal surgery, as unnecessarily complex and time consuming. In fact, a reasonably quick operator would have an average appendix out and the wound partially if not completely closed by the time one who followed Hirst's method had the appendix in the field of vision.

There is little else to criticise either in the choice of operative methods or the manner of their presentation. The illustrations are really excellent and so nearly explain themselves that but little text is necessary. The author's method of opening and treating extensive breast abscesses appeals to the reviewer except when plain gauze drains are advised in the later stages of treatment; for Soresi and others have shown that plain gauze, unless coated with paraffin or some other substance, often acts as a plug rather than a drain. The description and illustration of the removal of the breast for malignancy are largely taken from Deaver and McFarland's "The Breast." The text on this subject will bear further elaboration and at least two other methods of technique should be illustrated.

Hirst's Atlas should form an excellent aid to both students and operators.

ENGEBNISSE DER GESAMTEN MEDIZIN. Unter Mitarbeit hervorragender Fachgelehrten herausgegeben von Prof. Dr. TH. BRUGSCH. Erster Band. Berlin and Vienna: Urban und Schwarzenberg, 1920.

THE series of "Ergebnisse" which begins with the present volume is intended to provide for internal medicine the same valuable service that is already afforded by similar publications in the departments of physiology and pathology. It consists of brief monographs on widely differing topics by authors especially qualified to deal with them, and to report not only recent progress but also to discuss in detail subjects not usually treated at length in the ordinary handbooks. The present volume contains tweny-five such articles, all by well known writers, and comprises a great fund of highly valuable material. The project represents a very important contribution to medical literature.

THE SURGICAL CLINICS OF CHICAGO. Vol. III, No. 6, December, 1919. Octavo of 216 pages, with 63 illustrations. Index. Published bimonthly. Philadelphia and London: W. B. Saunders Company.

AMONG the interesting features of this number of the Clinics are Bevan's remarks on the value (relatively slight, in his opinion) of the *x*-ray in the diagnosis of gallstones; Eisendrath and Goodkind's report of a case and discussion of acute and subacute pancreatitis; Strauss's cases and discussion of the surgical treatment of gastric and duodenal ulcer, with a new method of pyloroplasty; Carl Beck's report of a case of diverticulum of the urinary bladder in an inguinal hernia, and another of gangrenous hernia of bladder and intestine; Speed's case and discussion of elephantiasis nostras; McWhorter's case and discussion of osteomyelitis with variation in growth of the femur following separation of the distal epiphysis; Harsha's case and discussion of acromegaly; and Woolston and White's report of 1000 patients operated on for tubal infection. This last article is very brief, and it would seem that with the study of so many cases it should have been made much more valuable.

DISEASES OF THE NERVOUS SYSTEM. A Text-book of Neurology and Psychiatry, by SMITH ELY JELLIFFE, M.D., Ph.D., formerly Professor of Psychiatry, Fordham University, New York, and formerly Adjunct Professor of Diseases of the Mind and Nervous System, New York Post-Graduate Medical School and Hospital, and WILLIAM A. WHITE, M.D., Superintendent of St. Elizabeth's Hospital, Washington, D. C.; Professor of Nervous and Mental Diseases, Georgetown University; and Lecturer on Psychiatry, U. S. Army and U. S. Navy Medical Schools. Third Edition, revised, rewritten and enlarged. Illustrated with 470 engravings and 12 plates. Philadelphia and New York; Lea and Febiger, 1919.

IT is only a few years since the first edition of this epoch-making work appeared, created a large audience which soon demanded a second edition, has devoured that, and now has called for a third edition. This has been carefully prepared and thoroughly revised in accordance with the last word in these allied subjects. In his recent Presidential Address to the New York Neurological Society, Walter Timme deplored the lagging behind of neurology, its contentment with old forms, and its infinitesimal progress compared with other branches of medicine. He spoke the truth, but it is one which would be non-existent were there more works such as this one.

The present edition bears especially the marks of revision in its sections dealing with vegetative neurology and endocrinology. Furthermore, the vast clinical experience of injuries to peripheral nerves afforded by the Great War has resulted in a greatly improved and elaborated discussion of sensorimotor neurology. In the part devoted to psychiatry the authors have gotten even further away than before from the old Kraepelinian school and lean heavily on interpretation rather than description. While this section is divided into the old groups of dementia precox, manic-depressive, etc., the authors mention and recommend Kemp's so-called mechanistic classification without seeming to realize that this is after all descriptive psychiatry carried to the *nth* power. It is as if physical diseases were minutely subdivided into minute groups, each symptom sufficing for a class.

MANUAL OF TROPICAL MEDICINE. By ALDO CASTELLANI, C.M.G., M.D., M.R.C.P. Lecturer at the London School of Tropical Medicine; Emeritus Professor Ceylon Medical School; Lieut. Colonel R.I.M.N.S (Balkan Zone); Director of Clinique for Tropical Diseases and Physician to Colombo General Hospital 1903-1915; Member of Royal Society's Commission in Uganda 1902-1903; and ALBERT J. CHALMERS, M.D., F.R.C.S., D.P.H., Director, Welcome Tropical Research Laboratories (Soudan Government); Ceylon Medical Service 1901-1911; Holt Fellow, University College, Liverpool, 1890; Medical Officer, Gold Coast Colony, 1897-1901. Third Edition. New York: William Wood and Company, 1920.

IT is several years since the second edition of this standard work was published, the long interval being occasioned not by a waning interest in tropical diseases, but by the interruption in all scientific work occasioned by the war. The time was not lost, however, for an opportunity has been afforded for the incorporation of much new material based upon the invaluable experience of the authors in their work with the armies in the Balkans and elsewhere where many of the diseases called tropical prevail. The addition of this new matter has increased the value of the book, which from the appearance of the first edition has been an indispensable guide to the student of the diseases of hot climates.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Twenty-First Annual Meeting, Held in Philadelphia, May 7 and 8, 1920.

First Session—Friday Morning, May 7.

THE PRESIDENT, DR. CHARLES E. DEM. SAJOUS OF PHILADELPHIA, IN THE CHAIR.

Dr. SAJOUS in opening the meeting said that this was the twenty-first birthday of the society. The time was auspicious to give the science of therapeutics its due. Its neglect and abandonment should be corrected and its due importance to medicine and to humanity at large should be recognized.

The Late Professor Horatio C. Wood.—Dr. HENRY BEATES then read the obituary of Professor Horatio C. Wood (see page 393). At the close of the reading the members stood as a mark of respect to the memory of Professor Wood.

Presidential Address.—Dr. CHARLES E. DEM. SAJOUS then delivered his address with the title: "The Abandonment of Therapeutics in Medical Schools, Due to Neglect of Is Curative Subdivision, Pharmaco-Endocrinology" (see page 463).

Tissue Acidosis vs. Blood Acidosis.—Dr. WILLIAM H. MERCUR of Pittsburgh, Pa., read this paper (see page 467).

Therapeutics of Decreasing Body Alkalinity.—Dr. WM. H. PORTER of New York City presented this communication (see page 471).

Dr. H. C. GORDINIER of Troy, N. Y., said he was present at a general meeting when the subject of acidosis was presented, and to many there present the subject as discussed seemed as if spoken in an unknown tongue. He had had the same experience with sodium bicarbonate. The urine was rendered neutral or alkaline, without change in the dyspnea. On the other hand, with the use of the citrates and plenty of water, there had followed a reduction or disappearance of the acidosis and the dyspnea.

Dr. E. E. CORNWALL of Brooklyn said he would like to ask a question. How did the carbohydrate in the diet guard against acidosis? How was it that the Esquimaux, whose diet contained abundant fat, but almost no carbohydrate, managed to escape acidosis? Could they use enough ammonia to save themselves? He sounded a warning against too much restriction of carbohydrate in non-diabetic conditions, on the pretext of protecting against carbohydrate indigestion, which he thought was somewhat of a fad, and was often carried too far; he cited a case of a woman of forty, who for indigestion and emaciation was put on a diet which contained a large amount of fat with a considerable amount of flesh, but was greatly restricted as to carbohydrate; the woman developed a typical and severe attack of acidosis. He referred to the post-operative diet of broth and tea or coffee, which was so generally used, and which naturally favored acidosis. He spoke of the end results of the metabolism of foodstuffs in respect to acidity and alkalinity. All animal flesh and eggs in the final combustion in the body showed an excess of acid over base, thus making for acidity; and cereals, though to a less extent, showed the same. All fruits, green vegetables, and roots in their final combustion showed an excess of base over acid, thus supporting the alkaline reserves of the body; and milk, though to a less extent showed the same. From which it appeared that food from the animal kingdom, with the exception of milk, made for acidity in the body, and food from the vegetable kingdom, with the exception of cereals, made for alkalinity. A balanced diet, which would safeguard the alkalinity of the body consequently must contain a sufficiency of the foods of the alkaline class, which practically meant that they must contain a sufficiency of fruits and green vegetables, and not too great a preponderance of flesh and bread. Milk, Nature's prepared food, was safely alkaline, but not sufficiently so to offset the acid tendency of a diet containing much flesh. Green vegetables and fruits were the most effective alkalinizers, and also important sources of vitamines.

Dr. MERCUR, in closing, said that he had written this paper to learn something about acidosis. He had not learned the treatment of acidosis with food. The only diuretic he had used was water. He gave bicarbonate of soda, well diluted, but shifted to some other alkalies later, citrate of potash, or pure kaolin, 15 to 30 grains. It was necessary to have a free activity of the kidneys.

Dr. PORTER said that it was necessary to have trisodium phosphate. Animal foods were deficient in trisodium phosphates and vegetable foods were rich in them, and these fixed the alkalies in the tissues. If the diet were deficient in these the bone tructure of children was affected and rickets followed.

Some Aspects of Hyperchlorhydria with Special Reference to the Treatment of This Affection.—Dr. JULIUS FRIEDENWALD of Baltimore read this paper. Hyperchlorhydria, he said, was an increase in the gastric hydrochloric acid secretion, produced during the period of digestion, and was formerly diagnosed whenever the hydrochloric acid of the gastric contents, after an Ewald test meal, exceeded 0.2 per cent., whether symptoms accompanied this state, or not. Many cases, however, had an acidity higher than 0.2 per cent., without presenting the symptomatology of hyperacidity, and many hypoacid cases showed symptoms of hyperacidity. Thus the normal and the hyperacid states differed in different individuals. According to some observers then, each individual stomach had its own degree of hyperacidity, what was sufficient for one, being more than sufficient for another. Another explanation was that in some persons the gastric mucosa was hypersensitive to hydrochloric acid and that also there must be some condition present to occasion the gastric hyperesthesia, the causative factor being either ulcer, retention, or hypersecretion on the one hand, or a sensory neurosis on the other. Recent observations, on interpretations of a series of curves of fractional analyses, had shown that there existed a hypersecretory type, a hyposecretory type, and a normal, or isosecretory type. A large group of healthy persons belonged to the first group. Also in health alternate cycles of activity and rest were noted—digestive and interdigestive periods. Psychic secretion was first produced, followed by true chemical secretion. At the beginning of peristalsis a gradual increase in acidity took place, which, at its height, was balanced by tryptic regurgitation. This occurred in the interdigestive phase. HCl at this stage was low. Soon after ingestion of food the digestive period was again accompanied by a rise in acidity. Very high acid curves could be compatible with perfect health; thus disease conditions, such as ulcer, were by no means accounted for by the hyperacid state, but were probably induced by vagotonia and disturbance of the sequence of digestive and interdigestive phases. Symptoms of gastric ulcer could be clinically improved without alteration of hyperacidity or hypersecretion, so that other conditions must be sought. These factors were probably to be found in the influence of the endocrine system, the thyroid possessing the power to intensify gastric function by influence on the terminal filaments of the vagus, and adrenal extract having an inhibitory action on the sympathetic. The involuntary nervous system controlled gastric secretion by maintaining a balance between activating and inhibitory innervation. The stimulation of the vagus group produced hyperchlorhydria; the inhibitory fiber's regulated secretion and spasm. Thus, in order properly to control hyperchlorhydria a correct estimation of the etiological factors was necessary. These included: (1) primary disturbance of the gastrointestinal tract; (2) constitutional and organic disease, including focal infection and reflex causes; (3) nervous affections; (4) disturbances of the endocrine glands. *Group one* included ulcer, pyloric obstructions, acid gastritis, atony and chronic constipation, disturbances caused by improper food and by tobacco. *Group two* contained cholelithiasis, nephrolithiasis, chronic appendicitis, chlorosis, cerebrospinal lesions, abdominal adhesions and genito-urinary infections. *Group three* comprised cases of mental strain, overwork, worry, neurasthenia, hysteria, and mental conditions. *Group four* covered the endocrinopathies. Until the latent cause of the disturbance was discovered, no proper therapy could be instituted. In regard to dietary regulation, it would seem important

to allow only such food as would avoid irritation of the gastric mucous membrane, thus reducing the hyperesthesia which was responsible for the hyperacidity. A liberal diet of proteins, carbohydrates, and fats was to be preferred, provided the food was not coarse. All organic acids and condiments were forbidden. Milk, eggs, and cheese could be suitably used to substitute meat proteins. Dr. Friedenwald presented tables (from Bickert) in which were given lists of foods strongly exciting gastric secretion, and those slightly stimulating it. Sugar was found helpful as it tended to reduce acidity. Fats, in the form of butter, cream, and olive oil were valuable. These patients should be allowed to eat five or six times daily. The Sippy cure was useful in a number of instances. Hygienic measures should not be neglected in cases of hyperchlorhydria. Fatigue and mental strain must be counteracted. Gastric lavage was not indicated in mild forms, but was valuable in the more severe cases. The use of alkalies was questionable, as in the end they tended to increase the maximal acidity. Bismuth and magnesia, or bismuth and soda might be of use. Atropine by mouth had no effect, but hypodermically produced quick results. Nerve sedatives, such as bromides, and valerianates were useful in gastric hyperesthesia and in hypoacid cases with symptoms of hyperacidity. Benzyl-benzoate was also useful in this connection. In conclusion it might be stated that clinical improvement might take place and yet the hyperchlorhydria remain stationary.

The Control of Hyperchlorhydria by Cholecystogastrostomy.—Dr. WAYNE W. BABCOCK of Philadelphia read this paper (see page 476).

Dr. MARTIN E. REHFUSS of Philadelphia said that one had heard a good deal regarding the question of hyperacidity. To attack this condition from the most accurate angle, one must have it well defined. Hyperacidity did not mean the same thing as hyperesthesia. There was a difference between the clinical findings and the enterogastric findings. The phenomena of pain, burning and distress might be produced in every case simply by increase of the actual acid. Such cases had been reported with total achylia and no acid. One-third of his own cases gave a low acid reaction. Thus there was a discrepancy between the subjective findings and the gastric acidity. It would seem therefore that the feeling of hyperacidity burning, and distress were brought into play by factors which has nothing to do with the titration of acid. At the Jefferson Medical College for five years they had been busy working on chemical tests and a large number of cases had been investigated. The effects of food on the normal stomach were examined in normal controls, and it was found that there might be very high acid within normal limits. To beef the average acid reaction was 120, and to eggs 80, in the normal individual. There must be other conditions influencing this question because some individuals had symptoms with high acid and others did not. He did not understand why bicarbonate of soda should affect acidosis nor how alcohols worked in the stomach. In persons with no acidity, soluble alcohols were very rapidly neutralized, followed by sugar secretion. This was true in regard to other forms. Bismuth over a long period of time was found to have a real sedative power. All foods, even water, were found to produce actual definite stimulation of the stomach and one-third of all human beings had an acid tendency, no matter what food was taken. One often found a higher acid reaction in a subject who complained of no symptoms. Study of a large number of normal people would reveal as high an acid as pathological cases. To-day there was confirmation of this fact coming from all sides. The conclusion was that it was not the quantity of acid, but the actual titratable acidity of the secretion that produced the symptoms. Dr. Babcock had spoken of his enterprising operation of cholecystogastrostomy. Dr. Babcock spoke as surgeons always spoke—that is, he said he had had so many cases, and they were all right. Last week a case was seen that was not all right. Dr. Babcock did unusually good surgical work, but Dr. Rehfuss said that as many patients came to him for postoperative gastric conditions as for gastric conditions. One-third of the cases, perhaps, were due to surgical interference. He would hesitate to allow a patient to undergo an operation which was not a physiological one. He could not conceive of the gall-bladder being attached to the stomach, with good result. While there might be a primary reduction of the acid, acid had not been proven to be a cause of ulcer. If it were, these operations might be justified, but it was not. Often there was a very high acid and no ulceration. One could introduce hydrochloric acid and there would be no result. He believed that hydrochloric acid was the cause of the chronicity of the ulcer, but until one found out what it was that made the mucous membrane lose its vitality, one did not know the cause of ulcer. The psychic secretion was so easily produced that one could get 240 to 800 gm. psychic secretion in the stomach without introducing any meal at all. This lasted from 60 to 80 minutes. The hypertonicity and hypersecretion were controlled by the vagus innervation, which supplied the stomach, gall-bladder, appendix, and duodenum. With vagus stimulation there was increased secretion in all of these organs. Chemical secretion persisted during the entire period of digestion. He believed that the question of gastric secretion would be explained by the influence of the ductless glands on the 10th nerve and sympathetic centers and by the influence of bacterial toxins on those centers.

Dr. JOHN C. HEMMETER of Baltimore said that this was a very capable presentation of the subject. A study of 6 years of ulcers of the stomach was very thorough. Ulcers could be produced experimentally. Sepsin, a product of fermentation of yeast, when injected into the blood produced ulcers of the stomach and duodenum. A toxin associated with skin burns would produce duodenal ulcers. The mucosa of the upper intestine was secretory and that of the stomach excretory. It was found that a circle was formed of the absorption of bile constituents. They were secreted in the duodenum and appeared in the circulation. Methylene blue could be absorbed and secreted for many hours. It was well known that the degree of acidity in the stomach could be controlled. He believed that Dr. Babcock should be given a chance to see what he could do in counteracting the chronicity of this condition.

Dr. KOONTZ of Philadelphia said that he would like to report two cases of cholecystogastrostomy. One was a patient who had had chronic dyspepsia 18 years. There were characteristic pain and distress, rapid loss of weight, and constantly shorter intervals between the attacks. The patient was admitted to the hospital and put under observation 10 days; total acidity was 100, free HCl 75, combined total acid 25. The *x*-ray showed ulcer of the pyloric sphincter. The patient was transferred to the surgical ward for operation. Cholecystogastrostomy was done. There was immediate relief of symptoms with a gain in weight. The gastric analysis after operation showed total acidity 32, free HCl 16, combined acidity 12. The *x*-ray showed the stomach emptied normally. The second case was diagnosed as one of gastric ulcer. A cholecystogastrostomy was done with anastomosis on the ulcerated curve. Following operation there was hematemesis. But later the patient gained. There was a condition of achlorhydria after operation. *X*-ray pictures of the results so far showed no abnormality of the gall-bladder. Convalescence was uneventful as regarded gall-bladder and stomach symptoms. There were three deaths: one cholemia with gallstones; one with appendicitis; one with intestinal tuberculosis. In other cases the operation had proved beneficial.

Dr. L. F. BISHOP of New York City said that he had the misfortune to teach chemistry before he became a physician, and as a young man it got him into all kinds of trouble. Chemistry was a sad story in the hands of many doctors. He was glad that Dr. Rehfuss' work was done by chemists. The doctors always stuck to the qualitative questions, whether things were acid or alkaline, they did not get on to quantitative methods. It was the same thing with the milk modification men. The point made by Dr. Rehfuss was important—not whether the contents were acid or alkaline, but how much acid was there. That was the whole question.

Dr. FRIEDENWALD, in closing, said that the society was to be congratulated on having Dr. Rehfuss to discuss these papers. His work on the gastric contents was well known and they were indebted to him for his

tube for fractional analysis. In regard to benzyl benzoate, it was useful in pylorospasm, in 20 drop doses in cold water, before meals. He did not know whether one preparation was better than another. In hyperacidity, as with many other conditions, analysis would find out whether it was due to the stomach itself or to some other cause. The symptoms could be relieved without reducing the amount of acidity in the stomach.

Dr. W. WAYNE BABCOCK, in closing, said that he was sorry he emphasized acidity in regard to this operation. He did not believe that acidity was the only factor in the production of gastric ulcers nor that alkalinity was the only protective factor in bile. There were a few ulcers that persisted despite anacidity. Most of the ulcers of the duodenum, however, were cured by a gastroenterostomy. What was the reason? It was at first thought that the gastroenterostomy relieved the patient by giving dependent drainage and by putting the ulcer at rest. Somebody, however, fed dogs pieces of meat tied to a string after the operation and found that the meat went out through the pylorus and then re-entered the stomach through the new opening and often repeatedly looped the loop, showing the tendency for food to pass out by the normal channel despite a large defendant opening in the stomach. Attempts made to tie off the pylorus permanently showed the strong tendency of the normal opening to reestablish itself. But experience had shown that duodenal ulcers heal after a gastroenterostomy, although the stomach emptied itself in the normal way. In other words, it was something that entered the stomach through the new stoma that gave relief, and not any new or better form of drainage. Evidently either the bile or pancreatic juice reentering the stomach contained the healing substance. These juices normally regurgitated back through the pylorus at the end of each meal and were the normal resting agents for the stomach. That these juices also protected the upper intestine was shown by the frequency with which ulcers of the duodenum and jejunum developed after bile and pancreatic juice had been diverted from these portions of the bowel. If gastroenterostomy or pyloroplasty relieved certain types of ulcers by permitting bile to enter the stomach, why not select an easier and more direct operation by anastomosing the gall-bladder directly with the ulcer-bearing area? In this way it seemed possible to protect and heal the large percentage of gastric ulcers that at present were not relieved by a gastroenterostomy. What was the effect of the nearly continuous entrance of bile into the stomach? So far as one could see the patients did as well as after gastroenterostomy, without the danger of that operation. Of 43 operations, only 2 or 3 cases had persistent symptoms, and none showed regurgitation or discomfort from the bile. The opening was made longitudinally, but quite large, and curiously the food as a rule did not seem to enter the gall-bladder. Of course it did not seem normal to have the bile thus enter the stomach, but for that matter it was not normal to have pylorospasm, hyperchlorhydria, or ulcer either, and as in other matters it seemed wise to select the lesser of two evils.

(To be continued.)

AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-seventh Annual Meeting, Held in Philadelphia, Pa., June 15, 16, and 17, 1920.

President's Address.—Dr. LAWRASON BROWN of Saranac Lake, N. Y., said that the success of a medical society depended upon whether its founders and directors possessed vision. Its first and foremost function was to bring together medical workers. Free intercourse among medical workers he believed to be essential to the development of an investigator's highest qualities. Its members being interested in more or less similar lines of work, it should function along the lines of group study of patients. He laid stress on the value of discussion, and thought it might be a good thing to have informal meetings where the younger men could ask questions of the more experienced. He expressed the opinion that fitness alone rendered a man's observations of value, by fitness meaning honesty, carefulness and willingness to one's observations, no matter how many cherished theories they might overthrow. He thought that a few carefully observed and recorded cases greatly outweighed a large number of cases stored in a memory. He believed that personal experience should be based upon carefully studied statistics of personal observation, and not upon personal impressions, which often covered a lack of recorded observation, and availed only for diagnosis. The phrase "personal experience," he said, should not be used as a cloak to cover one's ignorance of real personal experience.

Diagnosis of Myxedema.—Dr. JAMES M. ANDERS of Philadelphia presented a communication on this subject. In this paper he said that myxedema was insidious in its course, rendering an early diagnosis difficult, and he emphasized the importance of recognizing this disease, in view of the fact that a sovereign remedy for it existed. Unrecognized and long overlooked, cases with serious physical and mental developments would, he said, fail to respond in a satisfactory manner to appropriate measures. Statistical evidence would show that the condition was often overlooked. In the majority of cases some of the more characteristic features would be wanting. The author described incomplete types that might touch certain other diseases of the endocrine origin, and briefly considered the relation of myxedema to exophthalmic goiter. He believed efforts to stimulate interest in the subject to be both timely and important.

Dr. JOHN LLOYD of Rochester, N. Y., asked Dr. Anders whether he believed that there was an actual change produced in the kidneys by lack of thyroid secretion.

Dr. LAWRENCE LITCHFIELD of Pittsburgh said that it was very important to know the exact composition of the thyroid extract that one administered, different manufacturing chemists preparing these differently. Otherwise it would not be possible to keep accurate notes of what was being used and what the results were in each case. It was essential, he said, that the sheep's thyroid from which the extract was made should be normal and not goitrous.

Dr. DELANCEY ROCHESTER of Buffalo wished to know whether digestion was disturbed in the patient of Dr. Anders, because he himself had had several cases in which the administration of thyroid had done no good until a careful study of the digestion was made and a suitable diet prescribed.

Dr. H. R. M. LANDIS of Philadelphia thought that more stress should be laid on the expansive function of the thyroid. In order to use thyroid therapeutically one must obtain a more accurate idea regarding dosage. He had found that one dose would continue to act for fifteen days. The problem regarding digestion, referred to by Dr. Rochester, had not yet been worked out, but the speaker thought that the thyroid had much to do with the amount of acid in the system of the one receiving it.

Dr. ANDERS felt strongly that there could be no pathological changes produced in the kidneys. His case of myxedema and acromegaly showed a decided subacidity. He reiterated the fact that three-fourths of the reported cases of myxedema had been overlooked by one or more physicians before being recognized.

The Diagnosis and Treatment of Algid Malaria.—Dr. THOMAS D. COLEMAN of Augusta, Ga., defined pernicious malaria as a grave form of chronic malaria caused by the plasmodium, and always occurring in patients who had previously had malarial attacks or had resided where malaria prevailed. It would carry off the patient with horrifying suddenness. In all the classifications of pernicious malaria that he had seen he thought the tendency was to make too minute subdivisions, based on differences in degree, rather than of kind. He still adhered to the classification made by him in a former paper, namely: Comatose, algid, and hemoglobinuric (commonly called hemorrhagic). These types were produced by clumping of the organisms in different parts of the body. In the capillaries of the cerebrum it produced the comatose; in those of the medulla and basal ganglia, the algid; and

in the red blood cells of the general circulation, the hemoglobinuric. The diagnosis of algid malaria, he said, rested on the clinical and laboratory tests, the former embracing periodicity and the effects of quinine, and the latter the presence of the parasite or its products. The symptoms usually complained of included definite or indefinite attacks of fever or chills and fever, ill-defined pains in the back and limbs, sometimes headache, lack of inclination to exertion, loss of appetite, and indigestion with attacks of diarrhea or constipation; examination showed a diminution in the red blood corpuscles and hemoglobin, a decrease in the mononuclear leucocytes, flabbiness of the heart muscle, high-colored urine, containing an excess of urates and urobilin, enlargement of the spleen and liver, coating of the dorsum of the tongue and redness of its edges, yellowing of the conjunctiva, and harshness and greenish-yellow discoloration of the skin. Some cases would not show jaundice, but merely appeared anemic. The treatment should not be postponed until an explosion has occurred, but should be instituted in time to prevent the explosion. In cases presenting symptoms of chronic malaria, repeated search of the blood should be made for the plasmodium. Failure to find the parasite, however, would not negative the presence of malaria. The author had gotten very little satisfaction out of the use of any other drug than quinine, and did not think that time should be wasted in experimenting with anything else in such grave cases. The dose for adults should be five to ten grains every six hours for a week, then ten grains daily for three weeks or more. When given by mouth, in order to secure absorption, either a capsule or a solution should be used, because the tablet or sugar-coated pill would be apt to pass through the alimentary tract undissolved. In cases of nausea and vomiting, the drug should be given either intramuscularly or intravenously, five to ten grains being injected, in urgent cases, every six hours for a week. After this, ten to fifteen grains should be given daily for two or three weeks or more by mouth. In cases of such gravity, idiosyncrasies to quinine should not be considered, the author preferring to take his chances of combating any harmful tendencies of the quinine by the use of other remedies, including stimulants. He cited an interesting case in which the diagnosis was puzzling.

Dr. J. M. ANDERS of Philadelphia thought the true algid form should be distinguished from others. He had applied this term only to cases having a comatose condition and hemorrhage, which often ended in death in the course of a few hours. He agreed with Dr. Coleman that these pernicious forms were chronic types of malaria. He felt that all types should not be called pernicious, but only those having a subsequent explosion. Dr. Anders had often seen reports of cases of pernicious malaria not due to the tertian parasite. Cases of pernicious malaria should be treated, not only until the paroxysms had ceased to occur, but until the blood was thoroughly sterile. He preferred quinine to any other drug, and usually selected the intravenous route; but only when the injections could be given promptly, the time element being of the utmost importance.

Dr. THOMAS DARLINGTON of Washington, D. C., spoke of having had, many years before, about seven thousand workmen under his charge, all of whom suffered with malaria. There were not a few deaths among them, and he had seen death occur within twenty-four hours with hemorrhages from the eyes and nose. He felt, however, that thousands of cases of this kind, in which he had used quinine, were cured.

Dr. H. R. M. LANDIS of Philadelphia suggested the use of spinal puncture in cases of pernicious malaria in which it was difficult to find parasites in the blood. He thought that the risk was slight. In varying states, varying degrees of absorption might be encountered. In cases in which quinine could not be employed, he made use of methylene blue.

Dr. GORDON WILSON of Baltimore said that there was nothing in the classification given by Dr. Coleman to determine the type of organism producing the disease. While most cases could be placed under one of the three classes mentioned, one now and then met with irregular types that did not seem to fall into any of these classes. In such circumstances it was only through finding the organism in the blood that one could arrive at the correct diagnosis. He believed quinine to be the only drug to use in these cases. By injecting fresh blood he had often saved the lives of these patients.

Dr. DELANCEY ROCHESTER of Buffalo asked how the solution of quinine for intravenous injection was prepared.

Dr. JOHN ELLIOTT of New Orleans said the striking feature of some cases of malignant malaria that he had had the opportunity of seeing a number of years ago was that hemoglobinuria was limited to the white people. The algid form was seen in the natives. Forty to fifty per cent. had parasites in the blood. In the algid type, parasites were seldom found. While tertian malaria was always amenable to treatment, the more malignant tropical form did not always respond.

Dr. COLEMAN, in closing the discussion, expressed himself as satisfied that he had seen several types of pernicious malaria. He did not think one was justified in employing spinal puncture, although some cases might be improved. In regard to Dr. Wilson's comment, Dr. Coleman said that in these irregular types the patient might have something else at the same time that he had malaria. While hemorrhages occurred in certain types of pernicious anemia, he did not consider this to be the same as hemoglobinuria. In making the preparation of quinine for injection, he said, most men used distilled water, though some preferred saline solution.

Postural Rest for Pulmonary Tuberculosis.—Drs. GERALD B. WEBB, ALEXIUS M. FOSTER, and G. BURTON GILBERT of Colorado Springs sent this paper, which was read by Dr. WEBB. It stated that rest had been proved to be of value in tuberculosis of the joints and of the larynx, and defined artificial pneumothorax as a method of applying rest to the lung affected with that disease. Physicians had never fully applied the principle of rest to the tuberculous lung. The majority of patients with pulmonary tuberculosis were apt to lie on the side of the lung that had little infection, the actively diseased lung being thereby allowed the greater movement. The authors described their method of applying practical rest to the lung by having the patient lie on the affected side, the results of this treatment they claimed, having been excellent.

Dr. DELANCEY ROCHESTER of Buffalo thought that the treatment by strapping the side was much more pleasant to the patient than that by postural rest. He called attention to the fact that almost every pneumonia patient would lie on the diseased side.

Dr. JAMES ALEXANDER MILLER of New York had used this postural rest idea, with the patient lying on the affected side, and, in addition, had had the patient lie on a pillow, gradually increasing the height of the rest by the use of bags of salt or sand. This rested the lung more completely than could be done by posture alone.

Dr. CHARLES L. MINOR of Asheville asked whether Dr. Webb had any experiments to show what the effect on the bad side was when patients were put on that side. Dr. Minor did not see that the rate of breathing would be affected thereby.

Dr. BERTRAM E. WATERS of New York asked whether Dr. Webb had found that the patients were unable to get a free drainage from the affected lung when this method was employed.

Dr. WALTER C. KLOTZ of Paris, France, wished to know whether Dr. Webb would make a comparison between immobilization by postural treatment and that by compression and pneumothorax.

Dr. PAUL E. RINGER of Asheville had found that ascitic patients, when moving over on the affected side, would begin to cough and become uncomfortable. After lying in that position for a certain length of time they became sore and stiff; and he wondered how it would be possible to get them to lie that way for three or four months. He asked Dr. Webb whether it was the rest that he secured or the increased hyperemia produced by the postural treatment that caused the improvement. Dr. Phillips thought it doubtful whether there was much decrease in the amount of expansion of the lung. The greater part of the work of respiration being carried on by the diaphragm, it would be interesting to find out how much the mobility of the diaphragm was restricted on the diseased side.

Dr. JUDSON DALAND of Philadelphia said that the auscultation of the two bases in patients with pulmonary disease frequently showed distinct differences in the vesicular murmur. He felt sure that the lung on the inferior side could not function so well as that on the superior side, irrespective of the diaphragm.

Dr. CLEAVELAND FLOYD of Boston asked whether Dr. Webb had practised artificial pneumothorax, and if so whether he had found that putting the patients in this posture lengthened the interval at which he had to refill the chest.

Dr. LAWRASON BROWN of Saranac Lake said that he did not wish to deny that Dr. Webb's method did good, but he wondered how it worked, when he considered various points in the physiology of the lung. The part that moved most was the posterior part of the apex, and the apex did not move except through the sinking of the lung, which depended on the diaphragm. Dr. Brown also wanted to know how many cases Dr. Webb had tried the method on, and how many of these cases he had had success in.

Dr. CARROLL E. EDSON of Denver, in examining patients for suspected central pneumonia, had noticed that he got a sharper breathing on the lower side than on the upper. This had led him to suspect that the central pneumonia was on the side on which it later proved not to be. He wondered why, if the expansion of the lower and inner portion was due wholly to the diaphragm, it should move more with the weight of the liver lying against it, so that it had to push this weight, rather than when the weight was working with it.

Dr. FRED H. HEISE of New York said that the class of cases that Dr. Webb had been treating were advanced cases with adhesions between the diaphragm and the pleura and between the pleura and the chest wall. This placed the diaphragm at a disadvantage and did not allow it to expand the lower portion of the lung properly.

Dr. J. MADISON TAYLOR of Philadelphia said that there were varying conditions, localized here and there, that must be taken into account more in giving medicine by mouth or in any other way. While it had been thought that the result of such administration was almost uniform distribution, such was not the case, as indicated by the researches of Sir Almroth Wright, what the latter had called dead corners preventing the distribution of fluids or making it difficult.

Dr. THOMAS D. COLEMAN of Augusta referred to the fact that the diameters of the chest were increased on inspiration in three directions. A practical application of this was to be found in the posture that a pneumonia patient would naturally take.

Dr. WEBB, closing the discussion, said that he used the pillow, but did not use sand bags. He did, however, use bags of shot, just a few ounces at first, and gradually increasing the amount up to two pounds. The bag was placed on the affected side when the patient was permitted to roll over on his back. He did not consider strapping satisfactory. In answer to Dr. Minor, Dr. Webb said that the respiratory rate decreased when the temperature went down, but was always above normal. No influence on it was exerted by pressure on the diseased side. In regard to drainage, it was their custom to have the patients roll over on the sound side, to promote drainage, especially if there was pus. Turning them on the bad side would make them cough, but they had to get accustomed to that posture. He started them with five minutes a day on the bad side and gradually increased. Seeing the results coming, the patients were willing to keep on with the treatment. He thought that if proper attention was paid by nurses and attendants there would be no trouble with sore sides. He imagined that there was some hyperemia, and that this had to do with the effect. In regard to the question of respiration in the affected lung, the vesicular murmur on that side would be shown by the stethoscope to be very quiet; whereas the breathing on the upper side would be exaggerated. Dr. Webb then stated that the disease was apt to be in the upper lobes at first. In health, the diaphragm would have a wide excursion on the recumbent side; but he did not think that this kept up. He considered the point about the splint-like action of the viscera important. The matter of adhesions, he stated, had been taken into consideration. He had found that the artificial pneumothorax cases were markedly decreased. Two hundred cases had been treated, and among these only three or four had had to have an artificial pneumothorax. Some of the cases were early ones, and among these they had three complete failures—not, however, due to the treatment, but to the indiscretions of the patients. The majority of the other one hundred and ninety-seven patients had an arrested condition and were on exercise.

Tuberculosis and Influenza.—Dr. JOHN B. HAWES, 2d, of Boston, from his experience and that of others during the influenza epidemic, drew the following conclusions with especial regard to tuberculosis: (1) Eternal vigilance the price of safety. One should regard any patient who came down with a cold or other acute symptom, whether he had tuberculosis or not, and whether he dwelt in or outside of a sanatorium, as a possible subject of influenza, and, at all events, a source of contagion. (2) Although he thought it quite probable that the tuberculous patient possessed a certain degree of immunity to influenza, one should not take this for granted, and should make every effort to prevent his contracting that disease. (3) He stated that the treatment of influenza was the same in a tuberculous as in a nontuberculous person. It should be based on rational lines of rest, elimination, and stimulation if necessary. It should be regarded as a serious, but by no means a hopeless or fatal, complication. (4) He considered postinfluenzal bronchitis and debility real and definite clinical entities, but thought that in many cases they served to disguise a newly awakened pulmonary tuberculosis. In every case in which either a cough or prolonged physical depression followed influenza the patient should be kept under careful and constant supervision. (5) The early diagnosis of pulmonary tuberculosis, he maintained, had been made increasingly difficult on account of influenza and its effects. While he admitted that many cases of tuberculosis had been discovered or made active on account of influenza, he was convinced that there were numerous patients who had been wrongly classed as consumptives owing to signs and symptoms, constitutional and referred to the lungs, that were really due to influenza and not to tuberculosis. He thought that care, conservation, and common sense were needed more than ever in handling this difficult problem.

Dr. CHARLES L. MINOR of Asheville said that his experience suggested that influenza woke up a latent tuberculosis. He had noticed no special immunity to influenza among tuberculous persons.

Dr. GORDON WILSON of Baltimore had seen practically no deaths in tuberculous patients in the influenza epidemic of 1918-19. In patients seen since then, who gave a history that influenza had started up a chronic cough, investigation had shown that the cough had been of long standing. His opinion was that after a severe epidemic or influenza with a high mortality rate, there was, if anything, a decreased number of cases of tuberculosis.

Dr. JAMES ALEXANDER MILLER of New York considered the value of the questionnaire method of obtaining information doubtful. He said that during the past ten years there had never been such a large number of cases of tuberculosis in the New York institutions or such a low death rate. He stated that a considerable number of cases, although they had suspicious symptoms, were found, after study and observation, to be postinfluenzal conditions, and not tuberculosis.

Dr. J. B. ELLIOTT of Toronto said that in a sanatorium where the nurses and attendants were prostrated by the epidemic, the tuberculous patients to a great extent escaped. This would look as if the tuberculous did escape contagion in most cases; but if they did contract the disease it had a very harmful effect on them.

Dr. J. PERKINS of Providence stated that influenza had obtained a foothold in the men's ward in the recent epidemic, and a good many of those with chronic tuberculosis had contracted the disease. In those that did get it it proved fatal through pneumonia.

Dr. CARROLL E. EDSON of Denver thought that some of these supposed cases of influenza might have been early pulmonary tuberculosis, the patient not having had influenza at all. Many cases of tuberculosis, latent to a certain point, would begin with an attack of fever, cough, and discomfort, simulating an acute ill-

ness. In attempting to differentiate between mild influenza and a sharp attack of central bronchitis, such as the patients might have had at any other time, he had found that three-fourths of those cases with a clinical diagnosis of influenza had shown the presence of acetone in the urine within twelve hours of the onset of the disease. The acetone continued present during convalescence until the patients really began to feel well.

Dr. ROCHESTER of Buffalo stated that he had found in most cases of influenza an early acidosis, and he had obtained better results by giving alkalies in these cases than in any other way.

Dr. WILLIAM LEROY DUNN of Asheville said that, although he was overseas at the time of the epidemic, his assistant had stated that among the tuberculous patients under his charge there had been no case that he was willing to say was influenza. The attendants and nurses in many cases, however, did have distinct influenza.

Dr. NATHANIEL E. WOOD of Boston said that in Boston the ravages of the influenza epidemic were confined almost entirely to the poorest sections, those from which tuberculous cases were always coming, and he thought it a fair assumption that many persons who later would have developed tuberculosis died during that epidemic. This would be a factor in bringing fewer tuberculosis cases to the sanatorium. Another factor might have been the higher wages, enabling the people to live in greater comfort.

Odds and Ends in Tuberculosis.—Dr. CHARLES O. PROBST of Columbus, Ohio, considered this subject under four heads: tuberculin, temperature, work and rest, and mental influences. While he supposed he would be considered old fashioned in advocating the use of tuberculin in the treatment of tuberculosis, he decided to mention a case in which an improvement of tuberculous eye trouble took place after the discontinuance of local treatment and the administration of tuberculin. In regard to fever, he said he did not feel sure that the normal temperature of the patient was always at the arrow mark on thermometers. He had had a patient who seemed in good health, in whom the temperature was at no time over 98°, and another who always had a temperature of 99°. He advocated the taking of the records every two hours for four days or more. He considered it possible that nervous patients who had been impressed with the importance of slight variations in temperature might give themselves psychical rises when they used the thermometer. Complete rest he did not consider necessary for slight elevations of temperature, if there were no other symptoms, believing that rest in tuberculosis was often overdone. In many cases, he stated, complete arrest of the disease had been accomplished without having the patient stop work. Consciously or unconsciously, he believed, all good physicians make use of psychotherapy, but few do so intelligently. He had heard the president, Dr. Brown, say he thought tuberculin would do good if one had more faith in it. Dr. Probst said that this meant, if he could inspire the patients with more faith in it. He considered the cure of the patients, by any means whatever, as the life work of the physician. Apropos of tuberculin, he mentioned another case, in which massive doses were given to a man with a tuberculide of the buttock, as large as the hand, with involvement of the larynx. The ulceration had resisted local treatment for two years; but in ten months' time, with tuberculin and local treatment, it entirely healed, and had remained so for six or seven years.

Occupation of the Active and Arrested Cases in Tuberculosis.—Dr. BAYART T. CRANE of Rutland, Mass., read this paper, which he divided into four sections, as follows: (*a*) Occupatoonal therapy for active cases; (*b*) choice of occupation for arrested cases; (*c*) an industrial colony for chronic fibroid cases; and (*d*) economic considerations. In considering the first of these, he said that sanatorium treatment would have more professional and lay friends if it were humanized, and if an effort were made to make the life there pleasanter to the patient. Occupation would be of value in this direction, and might also be to a certain extent curative. The term psychotherapy by occupation would better define the object of such a system, intended to alleviate the abnormal nervous states of the patients, such as restlessness, introspection, ennui, etc. He selected the amount of work that each patient was capable of performing, leaving to the instructor and the patient to choose the kind of work. He had found this system curative when other things had failed in about five per cent., and extremely valuable in fifty per cent. An attempt should be made to make these activities gainful to the extent of defraying the cost of the patient's maintenance. The economic problem of the occupation of the tuberculous being one of the largest with which humanity has to deal, the physician must participate in the solution of it, because the physical limitations of these patients were so subtle that the lay mind did not comprehend where safety stopped and danger began. He should be able to define the class of cases which, while still positive, could safely, within limitations, pursue partial or entire self support. He might not, however, have great knowledge of industrial conditions, and so be unable to advise the patient where to find employment that would not overtax his strength and would yet return a sufficient income to provide adequate nourishment and comfort. If the man could not fit the occupation, the occupation must be made to fit the man. An industrial colony should be the next great step in the fight against tuberculosis, and Dr. Crane said that such a colony was being planned in Rutland.

Dr. FRANK A. CRAIG of Philadelphia stated that an attempt had been made at the Phipps Institute, Philadelphia, to provide occupation for such cases; and that since then there had been established at White Haven a training school for nurses, enabling a certain number of tuberculous women to earn their living and retain their health. There are still, however, great need of some occupation for the male patients. The shirtwaist factory started in Philadelphia was not successful financially, although it was from the standpoint of the health of the patients, and it had to be discontinued.

Dr. E. O. OTIS of Boston referred to the fact that the Boston Therapeutic Association had secured the services of a woman who had done army work in this direction. The enterprise had been very successful. Most of the patients, being in the advanced stage of tuberculosis, welcomed anything that would give them something to do. The difficulty was to find something that could be easily made by these patients and that would be readily salable.

Dr. NATHANIEL E. WOOD of Boston said that one reason that Dr. Crane's work had been a success was that he had had the assistance of some business men, who had given their thought and energy to planning the making of things that could be readily sold.

Dr. J. H. ELLIOTT of Toronto made a plea for patients suffering with other chronic diseases of the chest, such as chronic bronchitis with recurrent attacks, emphysema, bronchiecstasis, etc. He thought that provision should be made to give them employment, as well as the tuberculous.

A Study of the Progressive Changes in the Aorta and Lung as Shown by X-Ray in Tuberculosis and Syphilis.—Drs. CLEAVELAND FLOYD, HORACE K. BOUTWELL, and R. L. LEONARD of Boston presented this paper, which was read by Dr. FLOYD. From this study, it seemed to these authors that every case having tuberculosis with syphilis should receive intensive syphilitic treatment, especially if the lesion was not typically one of tuberculosis. The presence of syphilis, they thought, might at times considerably aid in the production of fibrous tissue in the lung. Syphilitic dilatation of the aortic arch, even in well-marked instances, might be improved by prolonged and intensive treatment. Some of the radiograms that Dr. Floyd exhibited showed very little evidence of pulmonary syphilis. The first plate, however, showed very definite signs of changes in the aorta, the arch being much dilated. In three instances the authors found by the *x*-ray a beginning cavity formation.

Dr. DELANCEY ROCHESTER of Buffalo remarked that even before the days of the Wassermann and the *x*-ray the diagnosis of syphilis of the lung had been made. Further observations had led to the definite conclusion that some cases of tuberculosis improved under mercurial treatment.

Dr. WILLIAM CHARLES WHITE of Pittsburgh thought that other organisms than the tubercle bacillus and the *Spirocheta pallida* could produce the symptoms of tuberculosis of the lung. He believed that a thorough study should be made of the air organisms that could produce fibrosis in the lung.

Dr. CARROLL E. EDSON of Denver asked whether in these cases of fibrosis and indeterminate processes with the sputum examination negative to the tubercle bacillus, the examination had been carried out simply with the ordinary stain. He had been finding a large number of cases that had the clinical picture of chronic fibrous pneumonia, in which he did not find tubercle bacilli in the sputum with the ordinary stain, but by sedimentation and staining with the Funk-Weiss process he was able to find them.

Dr. LAWRASON BROWN of Saranac Lake stated that pathologists had always agreed with clinicians that syphilis of the lung was a thing that did not exist. He did not think the therapeutic test safe to go by. The fact that a man got better under antisyphilitic treatment was no evidence that he had syphilis, and not tuberculosis.

Dr. GERALD B. WEBB of Colorado Springs spoke of a case of proved syphilis of the lung that he had seen thirteen years ago in Gohn's Clinic. There were gummata found all through the lungs at postmortem.

Dr. FLOYD, in closing the discussion, said, in answer to Dr. Edson, that the Funk-Weiss stain had not been employed. One case had no expectoration, and in the cases of mixed infection the tubercle bacilli were found. He thought that unless the spirochetes could be demonstrated in the sputum one could not make a diagnosis of syphilis of the lung; and that even then these organisms might come from elsewhere. One must depend on the therapeutic test. One could be morally sure, and that was all.

A Study of Destruction and Repair in Pulmonary Tuberculosis.—Dr. BERTRAM H. WATERS of Loomis, N. Y., considered briefly the occurrence of either marked improvement or the reverse in a patient, often without the slightest apparent change in the environment or routine. He discussed this in rather a speculative way, and illustrated the accompanying pulmonary condition by means of stereograms. He insisted upon the value of the latter in frequently enabling one to forecast what were usually termed relapses, and suggested the importance of a study of the underlying biochemical factors that must precede these "relapses."

Dr. DAVID RUSSELL LYMAN of Wallingford, Conn., thought it difficult to find out what started a case on the downward path, when one had been watching it improving and thought it on the mend. Some way of measuring the definite chemical and physical resistance of the patient was needed, he thought. He had been worried to hear Dr. Waters say that he relied entirely on the *x*-ray, and was relieved to hear him say that he had noticed that the work the patient was doing was tiring him.

Gunshot Wound in Case of Artificial Pneumothorax.—Dr. J. B. ELLIOTT of Toronto, Can., reported a case of moderately advanced tubercle of the lung, for which an artificial pneumothorax was made, resulting in apparent cure. The man appeared so well, indeed, that he was taken into the military service and served in France, performing all the laborious duties incident to the life of a soldier. Finally he received a gunshot wound in the chest and underwent several operations. He was afterward referred to the author, who made a study of his case in order to see what further could be done. It was then discovered that he had an artificial pneumothorax, performed earlier. The case resulted in chronic empyema. The author showed slides illustrating the condition.

Acute Epidemic Encephalitis.—Drs. CHARLES H. MINER and STANLEY FREEMAN of Wilkes-Barre, Pa., presented this paper, which was read by Dr. MINER. It gave studies of a series of cases with marked vascular hypertension, with especial reference to their etiology. From these studies the authors had been led to believe that in any case presenting fever and cranial nerve paralysis (particularly of the third and seventh nerves), accompanied with stupor or lethargy and with muscular fibrillation or tremor, together with a masklike face, a diagnosis of enchepalitis should be seriously considered. They had found the spinal fluid practically normal in all the cases, but believed that spinal puncture should be done when possible, in order to exclude cerebrospinal and tuberculous meningitis, anterior poliomyelitis, and cerebrospinal syphilitis. While there were many other conditions that might be confused with acute epidemic encephalitis, the authors felt that the cases of that disease, as they had seen them, were so characteristic and had so uniformly the same symptom complex that the diagnosis could readily be made by one who had once seen the disease.

Dr. GEORGE MORRIS PIERSOL of Philadelphia considered the cardinal symptoms of lethargy, persistent headache, nervous involvement, etc., the criteria on which to base a diagnosis of acute encephalitis. He had been struck with the occurrence of spasm of the upper segment of the rectus muscle as a cause of the muscular twitchings sometimes seen in these cases. He considered it more than a coincidence that the disease had been reported with greater frequency after epidemics of influenza and suggested that a widespread epidemic of encephalitis might be in the making. In that case the importance of being able to make a correct diagnosis would be apparent.

Dr. JUDSON DALAND of Philadelphia said that his mind turned to the question as to whether the condition might not be influenzal, although the authors had stated that they were unable to trace any relationship between influenza and the cases of encephalitis that they saw. He thought it should be remembered that after every epidemic of influenza there was a large number of carriers, and that the absence of a history of these about a case did not prove that the patient did not come in contact with influenza.

Dr. WILLIAM D. ALSEVER of Syracuse emphasized the possibility of an acute onset, and related cases in which this had occurred. He then referred to the fact that the pathological changes in encephalitis were identical with those in African sleeping sickness, although the organism causing the latter could not be the etiological factor in these cases.

Dr. DELANCEY ROCHESTER of Buffalo emphasized the great importance of lumbar puncture in these cases, and reported an illustrative case in which the condition was proved to be specific meningitis.

Dr. THOMAS A. CLAYTON of Washington, D. C., said that, as in other diseases, it was the first cases seen that gave the greatest trouble in making the diagnosis. He thought there must be many mild cases that were unrecognized and recovered. He suggested that the unusually large number of cases of facial paralysis seen in the last year might be due to this disease. He did not believe that a positive diagnosis could be made without an examination of the spinal fluid, and had been surprised to find that in this series of cases there had not been a decided change in the spinal fluid. In the cases that he had himself seen there had been an increase in the globulin and in the number of lymphocytes.

Dr. CARROLL E. EDSON of Denver reported five cases of illness occurring at the same time in a family, four being typical influenza; and the other, with apparently the same onset, was a distinct case of encephalitis lethargica.

Dr. GORDON WILSON of Baltimore mentioned a case that had been diagnosed by three good doctors as one of postinfluenza psychosis, and was correctly diagnosed as encephalitis lethargica only on account of ptosis. He thought it a question whether many so-called cases of postinfluenzal psychosis were not encephalitis.

Dr. GUY HINSDALE of Hot Springs, Va., asked whether any instances of localized neuritis or of vasomotor paralysis or stasis had been noted in any of these cases.

Dr. CHARLES L. MINOR of Asheville asked concerning the infectiousness of these cases.

Dr. JAMES M. ANDERS of Philadelphia thought it could safely be assumed that this was a microbic infection. It should be regarded as communicable, and precautions should be taken to prevent its spread. He did not believe an abrupt onset to be so rare as one of the speakers had intimated. He then emphasized the fact that there seemed to be a prodromal stage of more or less excitement preceding the lethargic stage. In the stage of excitement, diplopia and ptosis were likely

to be present. The prognosis should be very guarded, as these cases ran no definite course.

Dr. ROBERT WILSON, Jr., of Charleston asked whether the authors of the paper had noticed in their cases the presence of rapid respiration. He had found this symptom constant in five cases that he had had the opportunity of observing, in one of which the respirations had reached forty or fifty a minute.

Dr. MINER, closing the discussion, stated that they had had a very severe epidemic, so that everyone had been exposed to it. They had not, however, found any positive history of a typical attack of marked influenza in any case later than a year or two previous. They had noted an apparently abrupt onset in many cases. On study, however, it was found that the patients had had prodromal symptoms. Dr. Miner then said that if he had understood Dr. Hinsdale's question correctly, they had found the conditions he had asked about.

Concerning the Diagnostic Value of Cardiac Murmurs.—Dr. GLENTWOOD REEVE BUTLER of Brooklyn thought that there must be a very large number of persons who were unhappy because of a mistaken diagnosis of valvular heart disease, usually mitral insufficiency, the mistake having been made because of the axiom that a systolic murmur at the apex spelled organic incompetence of the bicuspid valve. He said there were three chronological types of murmur: diastolic, presystolic, and systolic. In the majority of cases the presence of an aortic diastolic murmur afforded reliable evidence of aortic insufficiency, but even with this murmur present, it was not safe to make the diagnosis without the confirmatory evidence of a water-hammer pulse, throbbing carotids, capillary pulsation, and a pistol-shot sound in the femorals. Presystolic murmurs, he regarded as being usually untrustworthy. To make a diagnosis of mitral stenosis without a definite murmur was unjustifiable, he thought; but even here, he admitted, there were possibilities of error. If the usually reliable diastolic and presystolic murmurs lent themselves to occasional misinterpretation, so, to a vastly greater extent, would the multitude of systolic murmurs. Aortic systolic murmurs, the author stated, were diagnosed by many men as aortic stenosis, they forgetting that such murmurs were very common as the result of slight roughening of the valves or the root of the aorta. They might also be accidental or functional. In reality, aortic stenosis was a rather rare lesion. He considered pulmonary systolic murmurs substantially negligible in the ordinary run of cases. Only when a sign of congenital malformation was it indicative of organic disease. Apical systolic murmurs were claimed by the author to constitute the greatest stumbling block in the way of correct diagnosis. More often they were of cardiorespiratory production. Uncomplicated (primary) mitral insufficiency should be classed among the comparatively infrequent valve lesions. It should not be diagnosed unless, in addition to the murmur, there was evidence of cardiac hypertrophy.

Dr. LAWRENCE LITCHFIELD of Pittsburgh did not believe that it was possible to have a mitral stenosis without an hypertrophy of the left auricle, and felt certain that whenever there was hypertrophy of the left auricle there must be mitral stenosis.

Dr. F. R. PHILLIPS of Charleston had observed small orifices in perfectly sound aortic valves, which permitted a certain amount of fluid to regurgitate under pressure. He said that some years ago, Dr. Porter of New York had called attention to these small openings and the possibility of their creating murmurs. If by stenosis of the mitral valve Dr. Butler had meant something that would prevent the free entrance of blood, then Dr. Phillips had failed to see any instance of mitral stenosis in his laboratory.

Dr. J. PERKINS of Providence related a case that he had seen while on the Medical Advisory Board. The Board had previously passed this man, but later Dr. Perkins, by careful listening, was able to make out a presystolic murmur.

Dr. JUDSON DALAND of Philadelphia had been led to the conclusion that sometimes a pulmonic systolic murmur was due to pressure from a large artery on the pulmonary artery. He called attention to the fact that exercise would often aid in the diagnosis of a mild grade of mitral insufficiency, producing a temporary murmur; and that indeterminable or impure murmurs at the apex could be developed into clear-cut, blowing murmurs by exercise.

Dr. JAMES M. ANDERS of Philadelphia felt sure that any murmur heard in the mid-presystolic or mid-diastolic period was due to mitral stenosis. He stated that occasionally a diastolic murmur of great purity originated in the large veins near the heart.

Dr. J. B. ELLIOTT of Toronto said that one might suspect stenosis on account of the snapping character of the first sound. He suggested that the inhalation of a few minims of amyl nitrite would frequently cause a murmur to appear.

Dr. BUTLER, closing, said that he had referred to actual definite distortions of the valve, or actual organic permanent narrowing of the orifice. He felt that before one could make a diagnosis of a real, true organic mitral stenosis, one must have a presystolic or a mid-diastolic murmur.

The Ultimate Prognosis in Vascular Hypertension.—Dr. G. MORRIS PIERSOL of Philadelphia, in presenting this paper, said that the prognosis in cases of hypertension often depended in a large part on their etiology, the mortality being much greater in nephritics than in any other group, as among his cases five times as many of these had died as among those suffering from other conditions. None of his cases in the climacteric group had had a fatal termination. The period of time from first coming under observation until death was much less among the nephritics than among those with hypertension from other causes. The patient with the highest blood pressure among his cases was known to have had this high blood pressure for eleven years. In all, he studied 134 cases of persistent hypertension, and from this study he concluded that persistent high blood pressure was more common as the result of chronic renal disease than of other causes. He also found hypertension of renal origin somewhat more common in men than in women. Primary hypertension of the climacteric variety, if regarded as a type of hyperpiesis, would make primary hypertension appear to be twice as common in women as in men. The most common causes of death in cases of persistent hypertension were cerebral hemorrhage and cardiac failure. The height of the blood pressure alone would not furnish an adequate basis for prognosis.

Dr CARROLL C. EDSON of Denver asked whether Dr. Piersol had noted any difference in the prognosis with relation to diastolic pressure. In the cases that he had had, he thought that the symptomatology had as much relation to a persistent high diastolic pressure as to a high systolic pressure. He believed that with both a high systolic and a high diastolic pressure the patient was worse off, and the case should have a more unfavorable prognosis than if he had a high systolic pressure only.

Dr. JAMES ALEXANDER MILLER of New York thought that if a patient had a high diastolic and a low systolic pressure his case belonged in the cerebral group; but that with a high diastolic pressure and a corresponding pulse pressure, there was likely to be disturbances of the heart. These cases, he said, represented, in a general way, two groups.

Dr. PHILIP MARVEL of Atlantic City asked whether Dr. Piersol had made a record of the diastolic pressure, and what percentage of the cases studied were over one hundred diastolic. He cited a case that bore out the statement that glandular activity had much to do with the systolic, and perhaps diastolic pressure.

Dr. JUDSON DALAND of Philadelphia believed that primary, or essential, hypertension cases meant a group including various kinds of cases that were not quite understood. He thought that infection lasting two or three years could explain the hypertension in certain cases. Involvement of the ductless glands might also be productive of hypertension in some cases. He requested Dr. Piersol to mention, in closing, the frequency of sudden death in these cases.

Dr. CHARLES L. MINOR of Asheville said that he could not understand how the hypotension of tuberculosis could change into hypertension during the short time that nephritis existed in these cases. He could not believe that arteriosclerosis could have developed during this short period.

Dr. DELANCEY ROCHESTER of Buffalo asked Dr. Piersol what he had found in the eye-grounds, and what relation the findings had to the cases that went on to either death or recovery. He also wished to know what effect the diastolic pressure had in connection with the prognosis.

Dr. CHARLES H. MINER of Wilkes-Barre stated that the prognosis was better in women than in men, and asked Dr. Piersol to give the diagnosis of cases of glandular disease that were not hyperthyroidism.

Dr. PIERSOL, closing the discussion, said that it had occurred to him that it would have been better to have worked up the diastolic pressure more carefully, although both pressures were taken in all the cases. The diastolic pressure had been 110, or over twenty-six out of the forty-two that died, and in nineteen of the forty-two still living. Therefore, nearly the same proportion of patients in both groups had excessive diastolic pressure. As to the bearing of pulse pressure on fatal complications, he had no data. He had been unable to find any relationship, so far as the etiology was concerned, to the diastolic pressure. Some of the questions asked he had not considered in his paper, because he had not the temerity to do so—for instance, the cause of primary hypertension. He did not doubt that infection was a factor in its production. The only sudden deaths in his series were those in which it occurred after a tremendous cerebral hemorrhage or during an attack of angina pectoris. About seven cases had a sudden termination. In regard to the occurrence of hypertension in tuberculosis, he had felt that when a nephritis occurred, something happened to the metabolism that allowed substances to be retained that ought to be eliminated, and that these substances set up an irritation that produced primary or auricular spasm. Ten of the fatal cases had definite changes in their eye-grounds.

The Ductless Glands.—Dr. WILLIAM DUFFIELD ROBINSON of Philadelphia read a paper on this subject, in which he stated that when there was a lack of proper balance caused by the failure of the endocrine glands to function properly, most of the organs of the body would be adversely affected. The endocrine glands, he said, owed their power of stimulating activity in cells in near or distant parts of the body to the fact that they contained or secreted substances known as hormones, or excitants, which were of simple chemical composition, and could pass quickly through the walls of the bloodvessels. He classified these glands into (1) nutritive glands and (2) regulating and stimulating glands; the first were represented by the thyroid, thymus, and hypophysis, and the second by the adrenals. Hormones were classified as acute and chronic, the former being those of the adrenals and the posterior lobe of the pituitary, and the latter those of the anterior lobe of the pituitary and thyroid. The action excited by acutely acting hormones was of only short duration. The condition of the glands could be told by the amount of hormones they secreted. The hormones of one gland might act in association with or in antagonism to the hormones of other ductless glands. The author considered in detail the different endocrine glands and the conditions produced by hypersecretion and hyposecretion of each, and spoke of the interrelation existing between the hypophysis, or pituitary gland, and the thyroid, thymus, suprarenals, and sexual, or gonad, glands. The author then went on to state that when a hormone floated in the blood stream, the cells of that organ requiring this hormone would appropriate the amount it needed. When, however, more was required than was offered by the blood from the endocrine making this hormone, the endocrine making an analogous hormone would supply its hormone to the hungry cell. If these hormones were supplied artificially by giving the patient dried glands or active preparations made from them, the under-supplied cells would take the required number for normal use. He further stated that the emotions acted on the endocrines, and that the endocrines produced emotions. Dr. Robinson thought that what had been proved and what had been indicated as probable showed what wonderful possibilities the future might reveal. Later, this knowledge would no doubt be amplified, and it would be shown how potent in health and in the cause and cure of disease were the hormones of the ductless glands.

Dr. CHARLES C. DEM. SAJOUS of Philadelphia said that adrenalin would not bring up the blood-pressure unless it was abnormally low. He thought that the suggestion that the adrenal secretion was at the foundation of respiration was proving to be true. The pituitary gland was not a secreting organ, but one that had the power to govern the secretions of the other ductless glands. He took the position that one should respect experimental evidence and also take clinical evidence, pathology, and all other data into consideration before reaching conclusions.

Lymphocytosis as a Diagnostic Sign of Focal Infection.—Dr. JUDSON DALAND of Philadelphia stated that this was a preliminary communication, and that he expected to give another in the fall. Relative lymphocytosis, he stated, occurred in 54 per cent. of 100 cases of focal infection with systemic manifestations, but that in only 1 per cent. was the lymphocytosis absolute. Small lymphocytes were increased in 31 per cent., and large lymphocytes were increased in only 11 per cent., and large lymphocytes were decreased in 86 per cent. Leucopenia occurred in 56 per cent., and leucocytosis in only 9 per cent. Therefore, the first factor of importance diagnostically would be the increased number of small lymphocytes; and the second, the association with leucopenia. With these two factors joined, the value of the findings would be very great. Dr. Daland was of the opinion that if these figures were accepted it would be safe to state that constituted what might be called a leucocytic picture, having a certain diagnostic value. By means of it one could recognize the existence of a focus of infection and certain systemic conditions. One could not be sure that the systemic conditions were in distinct association with the focal infection, and must often be undecided whether one should do anything radical regarding the focus of infection. When, however, a lymphocytosis was found in the blood, with a leucopenia associated, he felt satisfied to recommend radical steps concerning the focus of infection. In a few cases he had been able to assure himself that all foci had been removed; and by making leucocytic counts at weekly intervals and at intervals of two weeks, for as long as two months, he had seen the picture in these cases restored to normal.

Dr. GEORGE M. PIERSOL of Philadelphia said that if Dr. Daland's experience were proved by other observations to be correct, this method would prove a most useful, practical, and readily available one. He thought that these results afforded a good example of the value of routine laboratory work in the course of one's practice.

Studies in Vibrations Causing Pulmonary Physical Signs.—Dr. CHARLES M. MONTGOMERY of Philadelphia stated that the physical signs investigated were normal and abnormal vocal fremitus and resonance, whispering pectoriloquy, and bronchial breathing, special attention being given to the following: (1) The difference in characteristics between the spoken voice and the normal pulmonary vocal resonance. (2 The phenomena of (a) the presence of normal vocal fremitus and resonance in the absence of whispering pectoriloquy and bronchial breathing found over normal lung, and (b) diminished vocal fremitus and resonance in association with whispering pectoriloquy and bronchial breathing found in certain pathological conditions.

Dr. JUDSON DALAND of Philadelphia spoke of a case that he had seen in which the anterior part of the chest had been removed for empyema, and he could see the heart beating. There was no lung in contact with the chest, except posteriorly, but one could get excellent vocal fremitus on that side. Dr. Daland thought, therefore, that vibrations of a coarse variety could be transmitted through the lungs and out to the hands.

Dr. J. H. ELLIOTT of Toronto asked whether Dr. Montgomery's idea that the vibrations from the vocal cords were carried to the chest through the bronchial walls was anything other than pure theory, because the speaker thought that the sound waves would be deflected in passing through tissues of varying density, such as the cartilage and the softer tissue of the bronchial walls. He though it more probable that the sound was carried by the air column in the bronchial tree. If these points could be settled, he said, it would help professors to explain to their students the physical

phenomena occurring during an examination of the chest.

Dr. MONTGOMERY, closing, said that there was no question of the great transmissibility of bone, even when surrounded by the muscles. One could get pectoriloquy from the cavity, although in contact with solid tissue all the way through. The speaker said that he had not meant to state that the vibration was carried from the vocal cords down along the walls of the bronchial tree, but that they went from the vocal cords by the aerial route to the walls of the bronchi. He did not know how far the vibrations were carried by direct conduction down the bronchial wall.

The Treatment of Tuberculosis of the Larynx.—Dr. ALEXIUS M. FOSTER of Colorado Springs devoted the principal part of his paper to a discussion of a laryngeal mirror that he had devised for reflecting the rays of the sun upon the diseased part of the larynx. This mirror was made of an alloy of aluminum and magnesium, which reflected 85 per cent. of the actinic rays and absorbed most of the heat rays. The treatment could be given to himself by the patient. The exposure was not longer than thirty seconds at first, and the length of time was gradually worked up to ten minutes. Thirteen cases were reported by the author, who felt that this solar laryngoscope, if properly supervised and supplemented by all the other accepted forms of treatment, constituted a very valuable aid in the treatment of laryngeal tuberculosis. In the absence of Dr. Foster, his paper was read by Dr. Gerald B. Webb of Colorado Springs.

Dr. DELANCEY ROCHESTER of Buffalo was connected with an institution in that city in which the Rollier treatment for tuberculosis was used. He said that they had applied that treatment to the outside of the throat, exposing the bare skin to the sun's rays. A great many patients had improved, and some had obtained complete recovery under this method of treatment.

Dr. CHARLES L. MINOR of Asheville had used the solar laryngoscope in two cases, and had been much pleased with the results. He thought that if doctors treating tuberculosis would always use a laryngoscope they would have better results. He had ceased to look on the treatment of tuberculosis of the larynx as hopeless, unless the pharynx was involved.

Dr. LAWRASON BROWN asked in how many cases this treatment had been applied.

Dr. WEBB, closing the discussion on Dr. Forster's paper, said that it had been applied in upward of seventy-five or one hundred cases. Except in end cases, they had had excellent results. Results were obtained in the larynx, even when the condition in the lung was not improving. He felt that with the lamp they could concentrate the actinic rays on the organ involved, and that it was this concentration that constituted the great value of the remedy. The other points referred to, he said, had all been brought out in the paper, every form of treatment having been considered.

The Use of Intravenous Injection of Calcium Chloride in the Treatment of Pulmonary Tuberculosis.—Drs. PAUL H. RINGER and CHARLES L. MINOR of Asheville stated that their own limited experience and that of others had convinced them that in calcium chloride they had a remedy that would frequently palliate and relieve; and that when they could diagnose their cases early, it might even prove curative. While the results that they presented were not brilliant, and while they were based on but a small number of cases, their significance was such as to encourage the authors to further use of the drug. They felt that they had prolonged the lives of some of their patients, and had made others far more comfortable by the use of this method of treatment. Consequently, they believed that a fair trial should be given it by those who saw enough of such cases to enable them to draw conclusions as to its value. At the same time, they hoped that the reason for its good effect might be worked out in the pharmaceutical laboratries. A table was given showing the results in their sixteen cases.

Dr. JOHN B. HAWES, 2d, of Boston wished to know on what theory this drug worked. It seemed to do no harm and a certain amount of good, and he thought it would be something that those not connected with sanatoria could use when their patients came back from these. He asked whether it was as simple an operation as colostomy, which sometimes accomplished remarkable results.

Dr. WALTER C. KLOTZ of Paris, France, thought that if it would shorten the coagulation period, the injection of calcium salts by the intravenous method would be useful on account of the distressing effects produced on the stomach when given by the mouth. He said that French physicians were still giving calcium salts with the idea of counteracting the demineralization that occurs in tuberculosis.

Dr. WILLIAM LEROY DUNN of Asheville had used calcium chloride in ten cases, in some of which he had obtained distinct and often more or less permanent improvement. In still others, however, there was absolutely no improvement at all. He thought that when the dosage and the interval between doses had been more carefully worked out a larger percentage of good results would be obtained.

Dr. CARROLL E. EDSON of Denver thought that if this were a curative measure, and not merely a palliative one, the intervals between doses should be shortening, rather than lengthening.

BERTRAM H. WATERS of Loomis, N. Y., was of the opinion that anything should be tried that offered any improvement whatever. He felt that he was getting about as good results by the use of calcium lactate by mouth as could be obtained by the injection of calcium chloride.

Dr. LAWRASON BROWN of Saranac Lake said that one should bear in mind that intestinal tuberculosis had long and remarkable periods of remission, and that it was hard to tell whether it was what was done for the patient or something within himself that worked the change.

Dr. MINOR said that their results had been so satisfactory that they felt that anyone handling such cases should give this method of treatment a fair trial. They had not been able to figure out any pharmacology with reference to calcium in intestinal tuberculosis, but hoped to find out something about it later.

Dr. RINGER, closing, said that they had looked on calcium chloride entirely from a palliative standpoint. The impression that they had gained that with the continuance of the use of the drug, it lost its effect, would be in line with that theory. They had rather strayed away from the principle at first adopted, to wa' for the reappearance of the diarrheic symptoms anc pain, and tried to anticipate them by giving the injections more frequently, hoping that this interval would work better.

Election of Officers.—The following officers were elected: *President*, Dr. Carroll E. Edson of Denver; *Secretary and Treasurer*, Dr. Arthur K. Stone of Framingham Center, Mass.; *Recorder*, Dr. John Lloyd of Rochester, N. Y.

The Association was invited to meet next year at Asheville, but the acceptance of this invitation will depend upon the action of the Council.

Syphilis and Lethargic Encephalitis.—Jeanselme states that the coexistence of these two affections in the same patient is difficult of diagnosis. Thus in a man of twenty-nine, an old syphilitic, there was a continuous somnolence with diffuse motor pareses in the extremities suggesting a cerebellar origin. There was plenty of evidence of nervous syphilis, such as headache and delirium and all in all had encephalitis been present it would have been almost impossible to recognize it. It was evidently decided that both affections coexisted.—*Gazette des Hôpitaux*.

Gangrene of the Penis in Old Men.—De San Antonio of Madrid saw recently two cases which much resembled each other and which were unlike anything he had hitherto seen. The first patient was a man of sixty-five who had contracted a venereal sore, which had evidently been vigorously cauterized, the resulting inflammation having been attended by sphacelation. The second patient was also over sixty, and was a stable helper, doing rough and dirty work and addicted to drink. The gangrene in his case was of the subpreputial type, beginning in an ulcer. In both cases the process was selflimited, recovery occurring under simple antiseptic measures.—*La Medicina Ibera*.

Miscellany.

Syphilis in Africa.—The entire history of syphilis in the African continent has yet to be written. The subject has been revived by the war, for many Africans took part in the latter on French soil and were treated for syphilis, ancient and recent. Roy, a well known writer on exotic medicine, contributes an article on the subject in the *Union médicale du Canada* for May, 1920, xlix, 5. He has personally visited twenty-two African colonies and found among certain aborigines that syphilis was termed the "white man's disease." Evidently in Southern African pure blood there is no tradition of any autochthonous malady. The author has found that syphilis is very rare in equatorial and periequatorial Africa, especially the hereditary form. It is almost certain that the disease was brought there in modern times by the whites and that it has made but little headway. This limits the subject of old African syphilis to the Northern and Northeastern regions. Among the theories of origin of European syphilis there was one which derived it from Northern Africa. There is no evidence that Portuguese navigators brought the disease from Africa in the XIV century, but the author believes that the great upheaval in Spain from the expulsion of the Moors in 1492 was responsible for much dissemination of the infection, although at the time Columbus had not yet returned from America. While admitting a pre-Columbian syphilis in America which may have found its way to Europe the author holds that East Asia is the cradle of the disease, which spread both East to the New World in prehistoric times and gradually westward, infecting in time Arabia and Northern Africa. It is impossible to differentiate between the older and post-Columbian syphilis in the early infection of North Africa, but the author insists, despite the recent propaganda of Bloch, that this part of the world was syphilised centuries before the Columbian era. The old immunity of South Africa may not extend to the Hottentot and Bushman, now largely extinct, which tribes have an infusion of Asiatic blood.

A Society for the Study of Influenza.—Announcement is made in *El Siglo Medico* that at a session of the Real Academia Nacional de Medicine of Spain on the 7th of last February it was decided to form a permanent committee for investigating the etiology, symptomatology, and therapy of influenza, which would have the scope of a national society and would fraternize with similar bodies in other countries. As none of the latter are mentioned by name we may infer that Spain has taken the initiative in the matter. In regard to the etiology it is assumed—although actively denied in some quarters—that influenza is truly endemic in an area which comprises Russian Turkestan and extends to the borders of China. From this focus it moves west on stated occasions. For some unknown reason it has never spread to the East and has never crossed Behring's Strait to attack North America. This immunity could result from the sparse population eastward or from the absence of trade routes. Having invaded Europe the germ remains behind in the organisms of the victims and gives rise to secondary waves of infection. This is shown in the so-called Spanish influenza, for Spain is not the natural home of the malady, yet during that episode it was Spain and not Turkestan which infected Europe. No one germ can be held responsible for influenza as a whole, this being evident from the bacteriological reports of widely separated countries. The protein character of the disease is shown by unusual experiences, as the mysterious death of a tuberculous subject in the first few days of the Spanish epidemic. Later it was apparent that the victim had been unable to withstand an attack of the new malady, which clinically was expressed only by extreme asthenia and some dyspnea. The death had been certified as due to tuberculosis before the real state of affairs had been recognized. In theory treatment should be almost synonymous with disintoxication by promoting the action of the skin, kidneys, intestines, and lungs, and this should be accomplished rapidly by intensive diaphoresis and by the injection of diuretics such as urea. In some cases venesection up to a pint of blood followed by intravenous serum injections will greatly stimulate diuresis. Next to this line of treatment abscess of fixation appears to be the logical remedy.

Belgian Students Entertained in Paris.—Eighty students from the University of Brussels were entertained by the medical students of the University of Paris in the Students' House last spring. Professor Roger, dean of the Medical Faculty, presided and the General Association of French Physicians co-operated in the function. A new orchestra composed of French medical students made its début on this occasion. Of the selections played Handel's Largo is singled out as especially well rendered. A number of students gave vocal selections, assisted by distinguished professionals, including women. Two of the latter, Mesdames Leconte and Granier, rendered *Gros Chagrin*, the chef d'œuvre of Courteline, regarded by the French as their greatest comic modern author. The decorations were by students and are highly commended. Of the eighty Belgian students of whom seventy-five were medical and five pharmaceutical, every one had a war record, and all wore decorations. They reached Paris Sunday, March 21, and as soon as they had been escorted to the Students' House, "wine of honor" was served. On the following Tuesday a banquet was held. One week later the party visited Versailles. During the interval hospitals and clinics were visited. The movement seems to have been motivated by the desire universally felt for a close alliance in the future between France and Belgium. There is also a tendency toward international federations of medical and other students throughout the world, the first step in this direction going back to 1900 at Paris. There is further a tendency toward Pan-Frankish and Pan-Latin rapprochements and toward an understanding between the Franks or French-speaking races on the one hand and the new Republics of Poland, Czecho-Slovakia and Jugo-Slavia and the kingdom of Greece. Dr. Helme, who reports the function, does not, however, assign any special significance to this event.

"SUBCONSCIOUSNESS" AND DREAMS.

BY HENRY RUTGERS MARSHALL, LHD., D.S.,

NEW YORK.

I.

THE conception of the existence of mentality of which we are not aware—usually spoken of as subconsciousness—is an hypothesis so widely accepted nowadays that it may not seem to require elucidation; nevertheless it may be well to consider briefly certain of the grounds we have for this acceptance, inasmuch as the hypothesis involves implications that are often overlooked.

If we study cases of clear consciousness, we find that some of them can be, and some cannot be, recalled.

I am perfectly sure that I talked with a man who was introduced to me yesterday, and that I constantly mentioned his name, which was then in clear consciousness; but to-day I cannot, for the life of me, recall his name.

Closely allied with such cases are others where we have no appreciation that any clear consciousness occurred in connection with them in the past, until the fact is proven by evidence apart from the state involved. I may say that I do not recall that I knew the stranger's name at the time of our conversation; but my introducer may remind me that I took his card, read it, and noted his address in my diary; and there I find it.

Again I may talk for an hour with the stranger without realizing that I have ever met him, and thus have before had clear consciousness of his personality. But the mention of Cambridge may lead me to say, "Why, I met you ten years ago at the Darwin celebration!" Such cases are closely allied with those last mentioned, but they differ in this: that in the case just mentioned I have no inkling whatever that any clear consciousness in regard to the matter had previously occurred, and will never appreciate the fact unless some unusual situation brings its recall. It will be at once realized that the cases last mentioned are of the type familiar to psychoanalysts. In comparing them with the other more common types of experience it becomes clear that in psychoanalysis we are dealing with phenomena that are not sharply differentiated from matters of everyday occurrence.

The time that elapses before such sudden recall as we have considered varies very greatly, and at times is so short that we are inclined to assume that the clear consciousness was there all the time, even when it was not appreciated; and this assumption is strengthened by the fact that in many cases close attention to states of clear consciousness results in the appearance, within the very body of the state considered, of elements which did not at first seem to be there. This is what happens in all cases of analysis.

All this quite naturally leads to the hypothesis that there is at all times a large amount of mentality which does not, and some which cannot, come into clear consciousness—mentality which is subconscious, to use the current phrase; an hypothesis which is strengthened in the fact that it offers an explanation of those cases where a conclusion which would normally be reached by processes of reasoning, by steps within clear consciousness, is sometimes reached without any clear consciousness of these initial steps. Such cases in the last generation were described by the term "unconscious cerebration," and call for no illustration here. It is worth noting, however, that they are closely allied to experiences that are familiar to all of us. We go to bed worried because of the apparent impossibility of finding the solution of some problem. We awaken the next morning with the solution clearly in mind.

II.

The strongest corroboration of the hypothesis under consideration is found, however, if we consider the nature of the brain activities which correspond with consciousness. We have much evidence that special mental items that are in clear consciousness exist in correspondence with activities in what we call certain special brain parts. Now the brain is a highly complex system of minor systems of nerve ganglia. It is so thoroughly systematized that we may speak of it as always active *as a whole*, while life lasts. Thus what we call a special brain activity is really no other than an emphatic activity within a part of an all-active system.

Correspondingly introspective analysis shows us also that consciousness is a psychic system of minor systems of simplex psychic parts; and it would thus appear that what we call a mental item in clear consciousness, which corresponds with a neururgic emphasis, is no other than a psychic emphasis within the systemic whole of the mentality of the moment under consideration.

As we are able to note the special emphatic brain activity only as standing in contrast with the mass of unemphatic activities in the brain as a whole, so we may assume that we note in clear consciousness those psychic emphases, or mental items, only as standing in contrast with a mass of unemphatic psychic parts, some of which are always too unemphatic to appear in clear consciousness.

If we agree that the active brain is thus thoroughly systematized, it is apparent that we cannot look upon any minor system within it as a quite separate entity which only at times comes into action. The most we can say is that upon occasion its efficiency becomes prominent.

Correspondingly, if we think of consciousness as thoroughly systematized, we cannot look upon any minor psychic system within it as a quite separate entity which upon occasion becomes efficient. In other words, we cannot conceive of the mind as a bundle of separate "faculties," as was once the habit of thought. And this view is accepted by all modern psychologists who are very wary of anything that looks like a return to the discredited "faculty psychology."

The assumption of the existence of subconscious mentality is again corroborated in the fact that it enables us to gain a clear conception of what happens when we experience a change of "threshold," as it is called. If, as you read this paper, the door of your library were suddenly burst open and you found yourself confronted by an assassin, the brain which had been mildly active in certain parts would become violently active in other parts—so violently active that the activities of the parts that were previously emphatic in relation to the whole brain situation would no longer be thus relatively emphatic. Correspondingly, in consciousness, the elements of the argument I have been placing before you would in such a case at once disappear from clear consciousness, to be displaced by very different and very vivid mental items; the steps in the argument would become too unemphatic to appear as psychic emphases, while the mental items relating to anger, or fear, would become the emphatic elements in the newly aroused mental setting.

It is to be noted here that the more widely separated the two grades of nerve activity are, the more unlikely is the recall, in the newly appearing mental phase, of the mental items of the displaced mental phase. A gentle knock on my library door drives out of my mind, for the moment only, the points I am here trying to make, and I presently return to my writing without difficulty. If, however, I were disturbed by a cry of fire, and rushed to extinguish a conflagration, the thought of the present moment would be so utterly lost in the vivid experiences of the fire fighter that, when I returned to my desk, I should almost certainly have to start the train of thought all over again.

One other important point must be noted here, viz., that the brain activities which we speak of as special activities are what they are partly because the are under the control of the central brain system. And correspondingly the mental items that appear in clear consciousness are what they are partly because they are under control, because they are manipulated, so to speak, are ordered, are more or less logically constrained, by the self.

III

Turning now to consider the application of these facts to the explanation of the nature of dreams, it is to be noted in the first place that, if we are justified in the position taken in Part II above, then in accepting the existence of subconscious mental states we do so on grounds that compel us to maintain that we are never lacking in some mode of consciousness so long as the brain is alive. The most that we can hold is that in conditions of coma and of deep sleep the consciousness is usually of such a nature that it cannot be recalled in our normal waking life.

In the second place; inasmuch as the conditions of clear consciousness in waking life are always coupled with some measure of central control, we may assume that this central control has to do with the appearance of clear consciousness, and that where such clear consciousness is lacking, central control must be wanting.

In the third place; we may note that of all shifting of "thresholds," one of the most extreme is the change from deep sleep to the waking state. We should therefore expect to find that after awakening it will be difficult to recall mental items belonging to the sleeping state. But we should except that, where the shifting of "threshold" involved in awakening is relatively gradual, certain mental items of the sleep consciousness will be at times likely to attach themselves by association with certain mental items of the wide-awake consciousness, and in such cases we should expect, when we awake, to observe the recall, in more or less clear form, of some of the items of the sleep consciousness.

Such recalls are what we call our dreams.

The correctness of this view is corroborated in many ways. In the first place it is to be noted that, if the transition from very deep sleep to wide-awakeness is very sudden, recall of the deep sleep mental items will be unlikely to occur. This would mean that we will not be aware of having been dreaming when we awake fully and suddenly from sound sleep. And this implication of our view is certainly corroborated by experience.

Again, we should expect to note in our dreams a lack of that central control which is a characteristic of our wide-awake consciousness; and this expectation is met in experience; for our dreams are very noticeably characterized by disconnectedness and haphazardness, by a fortuitous development of lightly related mental items without the critical selection which is characteristic of our wide-awake rational life.

That this view is correct is again indicated by certain waking experiences accompanying lassitude, which is allied with the sleep state. Then we, more or less deliberately, relax the central control, "letting ourselves go" as we say. Then the imagination tends to run riot, and we experience mental streams so clearly allied with our dream streams that they are actually colloquially spoken of as "day dreams."

It thus appears that the nature of our dreams is clearly statable in terms of that part of consciousness of which we are aware. As Bergson well says, "The birth of a dream is then no mystery. It resembles the birth of all our perceptions. The mechanism of the dream is the same, in general, as that of normal perception." As in wide-awake life we build up in a flash the most complex of mental structures around some very simple percept, so we do in our dream life; this being describable, in the one case as in the other, as the sudden formation of a new mental pattern due to the emphasis of efficiencies already existing but unrecognized.

Some of our dreams are more or less coherent

and logical, others are not; and this is true also of the mental streams of waking life. In the main, however, our dreams are incoherent and non-logical, lacking the central control characteristic of our wide-awake life which we think of as the normal state of our consciousness.

That in dreams we often revive mental streams that have long since faded into the body of subawareness is merely proof of the fact that the readjustment of efficiencies that occurred in that dim past were permanent readjustments.

That the dream consciousness is closely related to the consciousness of insanity is natural in consideration of the fact that insanity is in the main evidenced by a lack of control by the ego system, which we have seen is also a characteristic of the dream consciousness.

IV

In closing I may perhaps be allowed to quote some sections of an article already published by me in England in *Mind* N. S. No. 98, indicating the relation of this view to that brought into prominence by Freud.

In his "The Interpretation of Dreams" (to which page numbers refer) he asks us to make a sharp distinction between consciousness, "foreconsciousness" and the unconscious. It will be apparent from what I have said above in relation to the "faculty psychology" that I see no ground for making this distinction.

Stripped of all illustrative material, Freud's theory may be stated as follows. His main interest is centered upon the thesis that every dream is the fulfillment of an unconscious wish. He conceives of this wish as an active entity which strives to rise into full consciousness and to effect its realization, this being thwarted by the action of another entity which he designates as the "censor." "The psychic activity in dream formation resolves itself into two functions—the provision of the dream thoughts" which are unconscious, "and the transformation of these into the dream content." This latter activity is "peculiar to dream life and characteristic of it, . . . something qualitatively altogether different from waking thought, and therefore not in any way comparable to it. It does not, in general, think, calculate, or judge at all, but limits itself to transforming. . . . This product, the dream, must at any cost be withdrawn from the censor" (p. 401 f.); this being accomplished by a variety of devices. The dream under his view would not occur unless it had a special function, which is thus described: "The dream has taken it upon itself to bring the liberated excitement of the unconscious back under the domination of the foreconscious; it thus affords relief for the excitement of the unconscious, and acts as a safety-valve for the latter" (p. 457 f.).

In all this Freud gives especial prominence to the conception of "the censor" which is described as a psychic system, or clever psychic entity, which resists the "penetration to consciousness of the dream thoughts" (p. 409), and which our author likens (p. 419) "to the Russian newspaper censor on the frontier, who allows to fall into the hands of his protected readers only those foreign journals that have passed under the black pencil." When the censor fears that the dream thought will escape his vigilance he resorts to all sorts of artifices to forestall its persistency. He changes the dream so that it becomes repugnant rather than attractive (p. 135). He molds the dream by distortion (p. 226); by displacement and condensation (p. 286 f.); by substitutions (p. 314); by the suppression and inversion of pleasure-pain and emotional reactions (p. 375); by making it appear foolish and disconnected (pp. 339 f., 419 f.); by forcing us to forget it upon awakening (p. 410 f.). Never, indeed, should we have a dream but for the fact that "the sleeping state makes dream formation possible by diminishing the endopsychic factor" (p. 416).

It seems clear that the psychologist must see in this theory the building of a huge structure upon a very slim and unstable foundation. It is to be agreed, of course, that the psychic system of which we are aware in waking life, molded as it has been, and is, by the social influences that surround us, prevents the fruition of desires, and frustrates the development of thought trains, which are inimical to our welfare as social beings. But this acknowledgment does not warrant us in holding that this wideawake consciousness is an entity so separate and diverse from the other psychic systems within us as our author would have us believe. All the evidence before us leads to the view that consciousness is fundamentally of the same nature through and through; that differences of systemic form occur within it; but that these are always in some measure correlated and are constantly more or less influential in determining the nature of that field of consciousness of which we are aware; this being quite compatible with the fact that, when we feel consciousness to be less than fully alert, prominence is gained by other psychic systems than that which is evidenced in moments of full alertness.

Passing over the final labored and obscure elaboration of this censorship (p. 426 ff.), which points to another censor governing "the transition from the foreconscious to the occupation of consciousness" (p. 490), we may turn to the main thesis, viz., that "the content of the dream is the fulfillment of a wish; its motive is a wish" (p. 100). Mr. Carr has called attention to a looseness of thought here. The most that Freud can claim is that we have in dreams what Mr. Carr calls the indulgence, rather than the fulfillment, of a wish.

The author's thesis in this particular is based upon his analysis of dream contents which, if allowed to develop, very frequently, if not usually, bring into prominence some wish which in the dream is felt to be realized. This fact none will deny, but question at once arises whether this is a special characteristic of dream consciousness. It surely is true that the development of the thoughts which arise in every-day wideawake life also constantly yields wishes that are immediately followed by pictures of the consequences of their imagined fulfillment. In this characteristic of dream life we therefore find no unique psychic functioning.

But in dream life, as in wideawake life, there are many cases where wishes are not observable. This fact, however, does not balk our theorist, who warns us that his "doctrine does not rest upon the acceptance of the manifest dream content, but has reference to the thought content which is found to lie behind the dream by the process of interpretation"

(p. 114). And here he displays extraordinary ingenuity in ferreting out dream wishes where none at first appears, by methods which, by the way, would yield very similar results if applied to normal waking consciousness. In his other writings our author has given evidence of a morbid tendency to overemphasize the potency of erotic influences in all of experience, and in the field here considered the results of this preconception are conspicuous, leading him to improbable and revolting explanations. It is true that these influences are very powerful in our adult lives; it may be true also that they have been powerful in infantile life, and that their early activity may have resultants which are felt as we come to maturity. It is to be noted, however, that the traces thus left are likely to appear, not only in dream life, but also in wideawake life when we allow our thoughts to flow without restriction. All this may be granted, however, without forcing us to follow our author in his insistence that practically all such dream wishes must have this erotic origin.

Finally, when we turn to our author's thesis that the dream has a special function, we find ourselves naturally led to assume a sceptical attitude by the fact that throughout the whole of his studies evidence constantly appears which leads us to note the closest of relations between our wideawake and our dream consciousness. This our author accepts or denies as occasion requires. He agrees "that all the material composing the content of the dream in some way originates in experience" (p. 7); that "the experiences of the previous day furnish the immediate material for its content" (p. 192); that the dream thoughts "are usually found to be a complex of thoughts and memories of the most intricate possible construction, and to possess all the properties of the thought processes which are known to us from waking life" (p. 289); and even goes so far as to say that Aristotle was correct in holding that "the dream is a continuation of thinking in sleep" (p. 436). Yet, as we have seen before, he bases his theory upon the assumption that there is an activity in the transformation of dream thoughts into dream content which is "something qualitatively altogether different from waking thought, and therefore not in any way comparable to it;" and he finally asks us to believe that "it is quite impossible to explain the dream as a psychic process" (p. 405).

A REPORT OF ONE THOUSAND HEART PATIENTS SUBJECTED TO A COMPLETE CARDIAC EXAMINATION WITH AN ACCOUNT OF THE THERAPEUTIC RESULTS.*

By LOUIS FAUGÈRES BISHOP, A.M., M.D., Sc.D., F.A.C.P.,
NEW YORK.
CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY, PHYSICIAN TO THE LINCOLN HOSPITAL, NEW YORK.

THIS paper constitutes an attempt to formulate some points in the therapeutic instruction that the author has obtained from the study of the reaction of persons suffering from heart disease to such therapeutic procedures as were instituted while they were subjected to observations by modern cardiological methods. It has been found impracticable to classify them according to the standard of nomenclature adopted by hospitals. This is essentially founded upon pathological anatomy while all modern cardiological methods lay particular emphasis on function.

One of the most interesting points is connected with auricular heart conditions and centers around the use of digitalis. Auricular fibrillation occurred in 4.5 per cent. of the thousand and was usually treated with digitalis. In a large number of these hearts over a long period of time, it was observed that a very fair portion required much less digitalis as time went along and a few of them established a permanent partial heart block that made the use of the drug entirely unnecessary. This happened while the character of the disorder remained otherwise unchanged. Of course, in these conditions the continuous use of the drug has proved satisfactory when intelligently regulated, but there have also been other people who became unexpectedly well on the continuous use of the drug over periods covering years at a time. This has been true especially in older people who, before the use of digitalis was instituted, had been subject to frequent attacks of broken compensation, and yet when they took from a grain to a grain and a half of the powdered leaves every day have continued in remarkably good condition for a period of two or three years at a time and sometimes regained the normal cardiac rhythm. The conclusion is very definite that a senile heart reacts very well indeed to the continuous use of digitalis in small doses.

Two per cent. of the thousand cases examined showed by the electrocardiograph that they were suffering from bundle-branch lesions. Perhaps one-half of these were definitely benefited by the use of digitalis. Realizing the pathology of the disease as consisting of an interruption of the conductivity in one of the two branches of the auriculoventricular bundle, it might have been supposed that there was danger of producing complete block. This has not occurred in any instance and is to be explained by the fact that the trouble was founded upon structural change rather than chemical change. No doubt in a partial block due to toxic causes it would be very unwise to use digitalis because the muscle would probably be susceptible to this effect in a high degree from the drug. In the bundle-branch lesions founded on localized myocardial change it has not been found that the bundle was any more susceptible than in the normal heart.

Ventricular premature beats occurred in 4 per cent. of all these people and under so many different circumstances that it is difficult to form any classification. Certainly in the vast majority of instances they were not of serious clinical importance. They were found in people who are apparently perfectly well in every other respect and again in hearts far along the path of degeneration, and involved in conditions of fibrillation, tachycardia, and extremely weak heart muscle. No specific medication has been discovered for this condition, though in many persons it became

*Read at the annual meeting of the American Therapeutic Society, held in Philadelphia, May 8, 1920.

less marked or disappeared when the general metabolism of the individual was duly controlled.

The systematic use of the orthodiagram in conjunction with the electrocardiograph has revealed an unexpected frequency of conditions which cannot be otherwise interpreted except as congenital defects. These hearts, which are best called "infantile" because they represent a failure to pass entirely from the infantile to the adult type, are characterized by a relative right-sided predominance, by a typical shape of the heart when seen by *x*-ray, by a persistence of sinus arrhythmis, which, of course, is characteristic of childhood, by a history showing inability to take part in active exercises since childhood and a marked tendency to attacks of palpitation, and the presence of murmurs in the pulmonary area. Since my attention has been called to this type of heart, I have been encountering it at various ages and it seems to account for the development of very high blood pressure in some people, both young and old, where it is otherwise unexplainable. I do not venture to explain the exact mechanism, but this seems to happen for compensatory reasons. These people reacted very well to general hygienic management and to the circumstances that their condition was thoroughly explained to them after it had been somewhat of a mystery to many observers who had seen them previously.

Without the help of the orthodiagram and the electrocardiogram it seems to me that it is often absolutely impossible to classify these infantile hearts. I have not had time to determine the exact percentage that occurred in the group under consideration, but they were at least as frequent as the bundle-branch lesions.

The value of considering the heart as a mechanism whose energy is obtained by the chemical processes involved in making use of food products has become more and more evident. The heart is an engine actuated by the explosion of food products just as the automobile is actuated by the explosion of gas in its cylinders. The fuel that burns up cleanest and leaves the least residue, giving the greatest amount of energy, is the best fuel for the heart and for the engine. This is true in a high degree of starches, sugars, and fats, while the nitrogenous foods produce little energy in proportion to their bulk and leave an abundant residue of nitrogenous waste that must be dealt with. Nitrogenous food is like the bricks that go to make the furnace; as many as can be used for repair, are useful; any more than that are only in the way. It has seemed to me that hearts have manifested much more strength on a lactovegetarian diet than on a diet which consisted principally of flesh food.

This, however, raises the great question of flatulence that is ever present as the tormentor of the heart specialist. Through some nervous mechanism a weak heart muscle reflexly causes a debility of the stomach and intestines that deprives them of their ability to deal with gas and even promotes its formation. The popular idea is that this gas is due to the chemical changes that take place in carbohydrates and an attempt is often made to correct it by substituting nitrogenous foods. However, this in turn leads to a weakness of the heart and in the long run only increases the difficulty. On the other hand, an abundance of carbohydrates with the exercise that is allowable when the heart is properly sustained will lead in the long run to more gastric comfort and a much nearer approach to a condition of health. I have found the fear of carbohydrates a very important element to be dealt with in many persons with weak hearts and weak stomachs. The precise knowledge obtained by a complete examination gives us the courage to be radical in this matter.

In this group of heart patients which represents almost entirely those who had been pronounced such very definitely by several physicians before they came for examination, it has been found that constipation is often habitual and the general condition did not justify serious attempts to treat this in a radical way. For that reason the policy has been adopted in many instances of recommending the use of a laxative pill regularly every night in such dosage as was found necessary. The abuse of salines is so definite a factor in many cardiovascular-renal sufferers that we have absolutely discontinued the use of them and this with much satisfaction. Castor oil, however, has been used freely, but always with the admonition of allowing the bowels 48 hours' rest after its use. Paraldehyde in teaspoonful doses in water or some flavored mixture has been found a most satisfactory hypnotic and one that has not lead to any habit.

Nitroglycerin has been used freely in doses of 1/225th of a grain which the person is instructed to carry and use symptomatically for any emergency that might arise.

Theobromine sodium salicylate has proved very useful in some instances of marked edema, but it had to be given in a sufficient dosage—20 grains on the tongue followed by half a glass of water every two hours.

In dealing with flatulence we have used very freely a tablet of the following formula:

Sodium bicarbonate, pancreatin pure, papain, combined with flavoring and effervescent salt.

A constant effort has been made to improve the morale of heart sufferers and to teach them that exercise up to the point where it did no harm, did good—that physical fatigue might prove to them a great blessing as bringing natural rest and refreshment. As a matter of policy it has been found best in the practice devoted exclusively to heart conditions to forego the function of prognosis, except insofar as it consisted of an expression of confidence in the outcome of treatment. The demand for fixing a definite period of duration of life for the friends of heart patients has often been hard to satisfy, but most of them have yielded to the statement that our duty ended when we had made a complete study of the condition and advised the best treatment in our power.

In addition to everything else the psychotherapy of heart disease is of vast importance, but that itself, of course, does not allow of a very definite description.

This study has emphasized once again—first, the extreme value of digitalis as a remedy in cardiac disease with the conclusion that there is no necessity for a particular attempt to go outside

of digitalis in the use of analogous drugs. If any man ever could consider his mastery of the use of digitalis complete, then it would be time enough to take up something else. The second conclusion is the vast superiority of hygienic treatment, including hydrotherapy, graduated exercises, and psychotherapy, over an attempt at specific medication. The third conclusion is that at the time when heart patients reach the heart specialist it is usually too late to expect any special result from the so-called removal of specific causes as of focal infections.

I hope the Society will pardon this rather sketchy paper. When I sent the title to the secretary I had every intention of sitting down with my thousand records and becoming very statistical—instead of that I am submitting to you a lot of these records for your inspection.

109 East Sixty-first Street.

ENDOCRINOLOGY AND THE HEART.*

By THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK.

In the year 1893 I first made use of thyroid extract in the treatment of myxedema, achieving a result that seemed to me marvelously successful.[1] The cure was effected in 6 months. In 1896 I was equally forunate with it in a case of very pronounced Graves' disease.[2] The cure took about 2 years in this instance.

The adrenal gland I began using with success prior to 1905, as a heart stimulant, but did not, of course, find it so effective as digitalis. Under the name suprarenal extract I gave it three times a day, in doses of from 1 to 3 grains. I then used it alternately with some derivative of digitalis as a succedaneum. It may be remembered that Oliver and Schaefer[3], some years previously, found that the adrenal secretion stimulated the heart. Two years later, Abel[4] of Baltimore gave the name epinephrin to its potent principle, known now also as adrenalin, suprarenalin, adrenin, etc.

According to Sajous,[5] adrenalin activates the heart as follows: (1) By direct action of the glandular secretion on the muscular tissues of the cardiac cavities, and (2) by its stimulating power on the cerebrospinal nerves which govern the muscles of the heart.

Rhythmic contractions are thereby induced and maintained by the active principles. It is also indirectly activated by a certain proportion of the secretion when forced through the Thebesian channels into the walls of the heart, where it undergoes oxidation and conversion into material that eventually is controlled by the pituitary body.

There are three clinical manifestations of adrenal insufficiency, according to my personal classification: (1) the acute or temporary form, (2) the chronic or subacute, and (3) the recurring.

Among the prominent signs of adrenal insufficiency (hypoadrenia), are muscular asthenia, sensitiveness to cold, hypotension, weak cardiac action and pulse, subnormal temperature, loss of appetite, anemia, slow metabolism, indigestion, constipation, and psychoasthenia, perhaps Sergent's white line,

*Read at the annual meetng of the American Therapeutic Society, held in Philadelphia, May 8, 1920.

a dry skin, and no capacity for sustained effort. Now the pituitary (posterior lobe), as a remedial agent, raises depressed arterial tension and tends to correct arrhythmia. On the other hand, it is held that an excessive secretion leads to giantism and acromegalia, while a continued under-secretion produces defective growth and infantilism. The action of the posterior lobe is very similar to that of the adrenals in that it increases blood pressure, oxidation, metabolism, and nutrition, but it is much more continued than that of the adrenal, helping also to prolong the former's action. It is also connected in function with both the thyroid and parathyroids and some other ductless glands.

My experience in these cases has been limited, but the clinical results have been remarkable. Thus far I may say I have had no cases that have failed to yield more or less to treatment, as illustrated by the following:[1]

Case I.—L., a young lady of 30, was seen by me in 1916. She was pale, frail, and suffering from general and nervous debility. Pulse weak, but rate normal. Maximal systolic pressure, 90; hemoglobin, 70; some menorrhagia, controlled by cotarnine hydrochloride in ¾-grain doses, three times a day. After digitalis, strophanthus, iron, quinine, and strychnine had been used unsuccessfully, I gave Armour's dried adrenal gland in 2-grain doses, three times a day. The pulse quickly responded, the systolic pressure rising to 115, but there was a disagreeable fullness of the head. Accordingly, the dose of adrenal gland was reduced to 1½ grains three times a day, and there was added Armour's dried pituitary gland (posterior lobe) grain 1/10 with grain ½ of the citrate of quinine and iron. This prescription promptly effected a cure, and during the three years and more that have now elapsed, there has been no return of the adrenal inadequacy, and the patient has led an active and rather strenuous life. This I would call an acute case.

Case II.—A young lady, just out of school, was referred to me by her Canadian physician, in 1917. She was well developed, had grown very rapidly, weighed 132 pounds, and had been athletically inclined. During the preceding two years she had led an unusually active life. During this period her pulse had fallen to 45 at one time, and it was arrhythmic, while the systolic pressure was only 115. The family were neuropaths. On examination I found the radial rate 76-89; there were no intermissions, but the impulses were of uneven strength. Pressure, maximal systolic, 85; diastolic, 55; range, 30; hemoglobin, 55-60; amenorrhea; spinal anemia. I prescribed Parke, Davis & Co.'s dried adrenal gland, grain ¾, also Parke, Davis & Co.'s posterior lobe of the pituitary, grain 1/20; iron citrate, grain ¼. The adrenal was to be gradually increased to 2 grains, the posterior lobe of pituitary to 1 grain, if necessary, then iron and strychnine, if desirable to replace the citrate of iron. I saw her only once, but from a report subsequently received from her attending physician the young lady followed the adrenal and pituitary treatment for several months, improving slowly but gradually. At the time of his writing me, she was taking long walks and attending usual social functions, while the heart circulation was normal. Apparently it was only necessary for her to regulate her diet closely and avoid too much exercise, to be practically well, without having recourse again to endocrines. This might be called a subacute case.

Case III.—A married woman, now 58 years of age, who had applied to me for an eczema of her hands 23 years ago, and had been in a hospital for acute rheumatism and mitral disease at the age of 21, came under my care a second time in 1906. In 1916, I was called to see her again, as a surgical operation was under consideration. Medical methods, however, prevailed. The case was one of colonic impaction. Two years later she applied to me with right exophthalmus, tremor, facial paresis, and mental depression. There was no goiter. She was given 2¼ grains of thyroid extract per day, increased within a month, to 10 grains. Un-

der this treatment she was so far relieved as to be put on iron and quinine; though for cardiac weakness she was given digitalin and strophanthin in doses of grain 1/100 three times a day; later, digalen, and later still digitoxin. The maximum pressure rose to 122, but the pulse rate fell to 44 under the digitoxin, though under the iron and arsenic the hemoglobin had risen from 65 to 90. Digitalis preparations were then abandoned. In March last, the maximal pressure had fallen to 88. Under the thyroid extract, the exophthalmus had disappeared. Accordingly, dried adrenal gland, 1½ grains, and the posterior lobe of the pituitary, grain 1/10, were now given her three times a day. Improvement was immediate and marked. There was no further indication of adrenal inadequacy until recently, when the same treatment was adopted for one week, with relief of the symptoms. As, however, there is some cardiac inefficency, the patient is now taking digitalis, iron, and quinine. Here we have an example of hyperthyroidism followed by hypothyroidism of a recurring character.

The following case is illustrative of hypothyroidism successfully treated in a patient with aortic disease and diabetes.

CASE IV.—A well-known physician and teacher of this city, aged 57, weight 183 lbs., but himself under my care in December of 1915. He had been suffering from palpitation, but was at the time free from it and from pain of any kind referable to the heart. Radials firm but not hard; rhythm normal but rate quite variable; no impulse; aortic regurgitation but no thrill; apex 1½ centimeter inside of nipple. Liver low and large. Spleen not palpable. Tenderness over the region of the pancreas. Old pleurisy over lower right lobe. Grayish sputum in the morning. Had suffered previously from pneumonia. Intestinal indigestion. Systolic blood pressure 120, diastolic 90; pulse 30. Anemia was said to exist. He was put on digitalis, strophanthus, and glonoin, and advised to take regular outdoor exercise daily, be sparing in his diet, omitting starches and sugars. He returned to see me recently, suffering from a moderate diabetes mellitus, but he was not physically incapacitated for professional work. Blood pressure, systolic 136; diastolic 106 (pulse 30). According to my tables the systolic pressure was now about normal for his age, though the diastolic was high, while the pulse pressure still was low; in fact, exactly the same as it was when first taken by me. He was again put on the former treatment but returning in a week, the following symptoms, positive and negative, established the fact that in addition to his aortic disease, hypotension, intestinal indigestion, and anemia, he now had a subnormal temperature (96°), a dry skin, with incapacity for sustained work, and headaches, without goiter or tremor. Superficial fat abundant. Pulse rate variable, about 68. These new symptoms were those of hypothyroidism. His digitalis, strophanthus, and glonoin were, however, continued as before, three times a day in 1/100 grain doses of each, but to each tablet was added adrenalin, 1½ grains, and pituitary (posterior lobe), 1/10 grain. Nine days later came news over the telephone that he felt like another man. This case was probably one of hypothyroidism with an acute exacerbation.

These instances not only illustrate the close relationship Graves' disease bears to adrenal insufficiency, but show that thyroid extract, the adrenal gland, and the pituitary bodies can be relied on in the control of diseases that were formerly uncontrollable.

Owing to the unfavorable results that have sometimes followed the use of epinephrin hypodermically, and its inertness by the mouth, I prefer both the desiccated thyroid, adrenal, and pituitary glands in my practice. For some years I have been in the habit of giving Armour's or Parke Davis & Co.'s dried suprarenal extract in 2½-grain capsules, each, three times a day, adding 1/10 grain of the posterior lobe of the pituitary to supplement the action of the former.

As the chief objects of this paper have been to emphasize the clinical aspects of ductless-gland diseases, I will venture the following statements as the results of my experience.

1. Endocrinological vagaries are mostly confined to the female sex or to males of a feminine type.

2. While we have effectual results from the larger doses of the glandular extracts, such as are permissible according to the statements of our pharmaceutical handbooks, we may get better results by smaller dosage. It is better to begin with moderate doses of the thyroid, suprarenal gland, or pituitary, rather than to give large doses and have to suspend them temporarily or altogether, as has been done sometimes in the past.

3. The endocrines are more effective when given in combination with one another. The pituitary usually sets the others going.

4. In many cases, especially when anemia is marked, they may advantageously be combined with either iron, quinine, or strychnine.

5. The thyroid now in use in this country is mostly obtained from swine whose glands have been found to contain more free iodine than the sheep; the contents are more stable also; besides the thyroids of sheep are more apt to be diseased.

6. Thyroids are supposed to retain their active qualities, after desiccation, for 4 or 5 years, if properly preserved.

7. In desiccated suprarenals and pituitary bodies the active principles are less stable than in the thyroids. Whether the dry extracts preserve their therapeutic values for more than 18 months is not certain.

8. To ensure that all these glandular extracts are potent, as far as possible they should be obtained from reliable sources only. Otherwise they may be either harmful or inert. In my personal experience, however, I have invariably been furnished with satisfactory extracts by the great pharmaceutical houses.

Endocrinology is offering a promising field for investigation, and I feel confident that in the near future it will yield us additional facts of great practical importance. At the same time we should realize that notwithstanding it has already won for itself a positive position, it presents many unsolved problems. Under these circumstances it may easily be discredited by either ignorance of its present limitations or the too ardent claims of propagandists.

7 EAST EIGHTIETH STREET.

The Medical School at Porto Alegre, Brazil.—This institution was nominally founded in 1898, but apparently the formal opening has only recently taken place. This has been commemorated by the founding of a periodical, the *Archivos Rio-Grandensis de Medicina*. There is a numerous faculty of nearly fifty members, professors, clinical professors, and alternates. The college has just graduated a class of twenty students. The Medical Society of Porto Alegre was founded in 1908 and the *Archivos* is the official organ.

THE TREATMENT OF CARDIAC ARRHYTHMIA.*

By JAMES M. ANDERS, M.D., LL.D.

PHILADELPHIA, PA.

IN order to understand the various forms of abnormal heart mechanism, it is necessary to possess a knowledge of the normal mechanism. The heart beat is known to arise in the sinoauricular node, lying near to the mouth of the superior vena cava, the stimulus passing through the auriculo-ventricular conducting system, which has its origin in the septum of the auricle and carries the impulses from auricle to ventricle. Now, it is important to recollect that when lesions of the sino-auricular node exist and disturb the normal rhythmic heart beat, other centers lying in the junctional tissues between auricle and ventricle elaborate and send rhythmic impulses to the ventricle.

By means of electrocardiography we are able to determine definitely the direction of contraction of each subdivision of the heart, both in normal and abnormal cycles, and to record the same in curves. Our knowledge of the arrhythmias has been greatly advanced by the studies of Wenkelbach, Thomas Lewis, J. Mackenzie, Walter B. James, Lewellys F. Barker, Ross V. Patterson, Louis F. Bishop, James E. Talley, and others, as the result of observations with the electrocardiograph.

The treatment of the succeeding types of arrhythmia will be here discussed: (1) Sinus arrhythmia. (2) Extrasystole (premature contractions). (3) Auricular fibrillation. (4) Auricular flutter. (5) Heart-block. (6) Simple paroxysmal tachycardia. (7) Pulsus alternans.

1. *Sinus Arrhythmia.*—There are three recognized types: (*a*) Respiratory irregularity (for which there is no special treatment).

(*b*) Irregularity independent of respiration. This type is sometimes observed in healthy young subjects, and in connection with the slow pulse met with during convalescence from the acute affections, as well as after exercise. The indications are for rest and the use of a mild cardiac stimulant such as aromatic spirit of ammonia or strychnine, but not digitalis, which aggravates the condition.

(*c*) Cessation of the heart action. In this variety the standstill of the heart is accompanied by syncopal attacks. While the nature of the exciting cause is difficult to determine in special cases, in all it is the result of vagal discharges due to the action of some pathologic excitant, as pressure from an aneurysm (*e.g.* Neuberger and Edinger's case). These syncopal attacks should receive prompt attention when they occur. The patient should quickly assume the recumbent posture and diffusible stimulants should be administered. Causative treatment when practicable should be carried out.

2. *Extrasystole (Premature Contractions).*—The premature beat is associated with a great variety of conditions which cannot, owing to the exigencies of time and space, be considered, but it is to be recollected that it often accompanies grave diseases of the heart. For practical purposes the cases as a whole are divisible into two groups:

(*a*) Those associated with gross organic affections involving the valves and myocardium, and (*b*) those occurring in hearts which present no other symptoms, or the functional group. It has been well said, however, by Lewis that "The presence of premature contractions is an indication of disturbance of cardiac nutrition, whether temporary or permanent, but it is an aspect that should not be allowed undue prominence."[1]

(*a*) The intermissions that are met with in connection with grave affections of the heart are more commonly unperceived by the patient than those associated with functional disturbances of this organ.

Among etiologic factors are: fatigue in those predisposed; toxic agents such as tea, coffee, alcohol, and tobacco; certain drugs, *e.g.* digitalis, aconite, and reflex influences, which produce cardiac arrhythmia in affections of the liver, lungs, and kidneys. In the management of any given case, associated with valve lesions or other morbid states, it is important to search for the presence of one or more of the causative agencies mentioned above and, if found, to make a bold attempt to remove them. In a case of mitral incompetency with frequent extrasystole of ventricular origin as shown by the long pause, which I saw recently, the discontinuance of the immoderate use of coffee and tea as beverages was followed by decided improvement as to both frequency and severity of the premature contractions. Fatigue in sufferers from premature contractions belong to class (*a*) or those presenting organic lesions, tends to aggravate this symptom and should be guarded against by timely medical advice. It is also necessary to insist upon an added amount of physical and mental rest in such cases, since the labor of the organ has been increased by the increased frequency of the extrasystoles.

It is currently and correctly stated that digitalis is contraindicated as a rule in premature contraction, although cases that are encountered in the stage of decompensation of chronic valvulitis may be, as I have repeatedly observed, distinctly benefited by the drug. In such instances it should be combined with small doses of nitroglycerin—a remedy that also has a favorable effect in other forms of cardiac arrhythmia. The beneficial influence of digitalis in these cases is most probably due to an improved cardiac nutrition, which it brings about by improving the circulation in the heart muscle. The fact remains, however, that drugs, digitalis in particular, usually exert harmful effects in cases of extrasystole. In this type of the condition the bromides, which are often advised, should be omitted.

(*b*) Functional extrasystole or that of reflex origin: In these cases one may find a predominating neurotic element which must be combated. Again, there is often a history of the abuse of tea, coffee, alcohol, or tobacco, as before stated, all of which should be promptly discontinued. In the direction of causal treatment lies our principal hope of relieving the functional type of the condition. It has been more especially in cases of premature contractions occurring in hearts presenting no other signs, that were caused by excessive smoking, in which the writer has seen satisfactory results from a removal of the exciting cause.

*Read at the annual meeting of the American Therapeutic Association, Philadelphia, May 7 and 8, 1920.

A correction of the dietary in cases of reflex origin, *e.g.* those due to indigestible and coarse foodstuffs, sometimes proves effective. The condiiton is usually most troublesome after lying down at night, hence the evening meal should be quite light, dinner being taken at mid-day. The regulation of the habits and mode of life is important for all subjects of extrasystole. Remedies which aid digestion and general tonics when indicated should be employed. In examples of the functional type of extrasystole, methodic physical training, to strengthen the heart muscle and favor systemic development, is indicated.

3. *Auricular Fibrillation.*—In no other type of arrhythmia can the same degree of success be achieved as in auricular fibrillation. In this condition members of the digitalis group are clearly indicated, and the guide to the physician as regards sufficiency of dosage is the rate of heart beat. The immense majority of the cases in young subjects is caused by rheumatism or chorea, and here digitalis or one of its derivatives easily controls the rate by inducing a partial degree of "heart block," and thus preventing the impulses originating in the auricle from reaching the ventricle. Absolute rest in bed should also be insisted upon until the heart rate falls below 90 per minute. Indeed, in cases in which a favorable reaction to digitalis occurs, it is well to keep the patient at rest until the rate is nearly or quite normal. The drug should be continued after he rises from bed, the dose not to exceed that necessary to maintain the retardation.

In older subjects and in the non-rheumatic cases, digitalis sometimes fails to affect the heart rate owing to advanced myocardial degeneration as a rule, and rarely it causes nausea and other distressing gastric symptoms. In these recourse may be had to other remedies, *e.g.* strophanthus. Lewis, Bohan, and others laud in these circumstances tincture of strophanthus or tincture of squills in doses of 10 minims to be pushed in the same manner as digitalis. Universal experience, however, has shown them to be far less reliable than digitalis, hence they are to be given preference only in cases in which the latter has failed for the reasons above advanced. The use of strophanthinin intravenously has also been advocated in selected cases; the dose should not exceed gr. 1/100 at four to seven-day intervals.

The hygienic details, including the diet which should consist of nutritious, easily degestible solids, are matters of great importance. It is customary to find auricular fibrillation associated with marked cardiac dilatation, so that after the patient leaves his bed he should be warned of the unfavorable effect of fatigue, heavy manual labor, strenuous sports, and the like.

4. *Auricular Flutter.*—This condition, which is almost always associated with heart-block, may be paroxysmal in character. Its intimate association with heart-block is shown by the fact that the ventricular rate is either one-half or one-fourth that of the auricle. While many writers regard auricular flutter as a resultant of auricular fibrillation, they contend that it differs from the latter in three particulars: (*a*) the auricle contracts as a whole; (*b*) the regular stimulus originates in the usual area, while in fibrillation abnormal impulses arise in many areas; and (*c*) the extreme rate of the new auricular rhythm (200-350).

The treatment of this condition is similar to that of auricular fibrillation, namely by digitalis medication and absolute rest. It is to be recollected that if allowed to go untreated the condition tends to merge into auricular fibrillation.

5. *Heart-Block.*—The recognition of the grade of heart-block is necessary to successful management, and this is possible only by the use of the graphic methods furnished by the polygraph and galvanometer, which supply definite records of the systoles of the auricles and ventricles. The fact is now recognized that heart-block and the Adams-Stokes syndrome are not synonymous terms, but minor grades of the former exist without convulsions. The signs of myocardial and valvular lesions are also to be noted if present, before adopting any measure of treatment. The presence, when the block develops, of an acute infectious process or an actively progressive lesion, calls for rest in bed and appropriate treatment for the underlying causative conditions.

The more chronic forms associated with more or less dilatation and often dropsy, should receive cardiac stimulants, including digitalis. Despite the fact that digitalis increases the degree of the block, the drug is useful in these cases, even in those manifesting arterioscelerotic changes. Digitalis, as pointed out by Eggleston and others, is no longer regarded as a vasoconstrictor; neither does it raise the peripheral blood-pressure, as was formerly supposed, unless it be abnormally low. Salvarsan or neosalvarsan is used in cases of luetic origin when the myocardium is not too seriously damaged. Mercury is given during the intervals and the Wassermann test of the blood is to be carried out in the usual manner. The iodides have been exhibited in massive doses with good effect; they are used with advantage when salvarsan is contraindicated. For the fits when they occur little can be done, although numerous remedies have been counselled in the past, including adrenalin.

In the so-called functional form in which the heart muscle and valves are functionally efficient, atropine is employed; it often changes the ratio between the auricular and ventricular beat, so as to cause the block to disappear. The use of digitalis has been condemned in cases of partial block which it is apt to convert into a complete form, but as already intimated it may be given without restraint in such cases, if demanded by the presence of cardiac dilatation. Instances of incomplete heart-block, which are not uncommon, however, demand no special treatment *per se*, as a rule, As pointed out by Patterson,[3] in complete block, no hesitation in digitalis medication whatever need occur, "since the bundle function is already in complete abeyance."

In concluding, the management of individual cases of heart-block resolves itself into measures calculated to conserve the heart strength, but due consideration must also be given to the patient's general health and associated conditions.

6. *Simple Paroxysmal Tachycardia.*—In this type of disturbance of the normal mechanism a new center of pathologic impulse formation develops in some portion of the heart wall other than the pace-

maker, and dominates the movements of the whole heart, the rate varying from 100 to 200. The principal associated lesions are chronic valvulitis (mitral stenosis in particular) and myocardial degeneration. In about one-third of the cases no other signs of cardiac, arterial, or renal disease exist.

During the attacks, both local and general agencies are employed. It may be reasonably doubted whether we are aware of any remedy that will cut short a paroxysm of tachycardia. Given cases, more especially those in which more or less dilatation is associated, yield to digitalis in rapidly ascending dosage until nausea, diarrhea, or headache supervenes. After the toxc effects have subsided, following the method proposed by Lewis,[3] the maximum dose tolerated without discomfort may be exhibited for several weeks. Later on the prescribed amount may be reduced to about 5 drops thrice daily. Should the heart rate begin to rise, however, the dose is to be increased. Patterson[4] has well said that most sufferers from simple paroxysmal tachycardia will need digitalis continuously or intermittently for the rest of their lives in variable amounts. The claim has been made that the paroxysm has ceased shortly after the intravenous injection of digitalin (gr. 1/100) or strophanthin (gr. 1/250). It is well to recollect that digitalis acts by inducing a partial heart-block.

In all cases, other measures when the patient is first seen, such as rest in bed and those called for by special symptoms, must be instituted. In an example of tachycardia which fell under personal observation, a brisk purge with relief of marked flatulence, abolished the paroxysm.

In a small percentage of instances the assumption of a given posture proves effective, although it has not been my good fortune to witness a case thus apparently aborted. Firm pressure upon the right vagus nerve as it lies in the carotid sheath until the carotid pulse wave is obliterated, is worthy of a trial. I have observed excellent results from the application of an ice bag over the precordium in a few instances, and feel that this measure should never be omitted from consideration, at least. A mustard plaster may exert a beneficial effect, if precordial pains be complained of by the patient. The fact that spontaneous relief occurs abruptly in this condition makes our estimate of the value of the different agents advised, more or less conjectural.

7. *Pulsus Alternans.*—Alternation of the heart is of unknown origin, although it may be looked upon from the standpoint of treatment as a form of exhaustion from overtaxation—mental or physical, or both. Individual cases must therefore be subjected to a critical review with the object of ascertaining the causative factors. If found to be chiefly physical overwork, then an increased amount of bodily rest is demanded together with a curtailment of muscular exertion. On the other hand, cases due principally to mental overtaxation call for a lessening of the stress of mind, and a lengthening of the period of daily rest. Such patients often present associated morbid conditions, *e.g.* high blood pressure, renal disease, angina and Cheyne-Stokes breathing, and these are to be met on accepted therapeutic principles.

There is a class of cases of alternation of the heart in which the rate is accelerated; it may be associated with simple paroxysmal tachycardia. When it is an accompaniment of the latter disorder, the cautious use of digitalis is sometimes serviceable. In the more serious form seen in elderly subjects with a heart rate not above the normal limits, this drug is not to be advised. Here safety demands reliance upon rest, the while the heart's burden is lessened to the greatest possible extent.

THE PROBLEM OF THE AILING MEDICAL PROFESSION AND ITS SOLUTION.

BY JOSEPH BYRNE, M.D., M.R.C.S.,

NEW YORK.

PROFESSOR OF NEUROLOGY, FORDHAM UNIVERSITY MEDICAL SCHOOL.

WITHIN the past decade the author has frequently commented in public and private, on the unfriendly attitude of the laity in general to the medical profession. This attitude in recent years has constantly grown more and more hostile so that at the present time the younger members of the profession are almost ashamed to declare in a mixed gathering that they are regular practitioners of medicine lest by doing so they may offend the delicate sensibilities of some "healer" practising in the name of one or other of the various "scientific systems" of therapy now in vogue. But bad as it is this is not the worst feature of the situation. The younger men fired with the spirit of scientific achievement might afford to overlook the affected scorn of their rivals and of the uninformed public were it not for the deplorable fact that after long years of preparation they enter upon the practice of medicine only to find that what they had been taught in the medical school and the hospital is often more of a hindrance than a help to them in their struggle against competitors whose "system of practice" relieves them of the necessity of diagnosing disease and whose only concern is the routine employment of some form or other of remedy usually of a mechanical nature. A former student of mine who is about to open an office consulted me recently as to the selection of a location. He had gone through the regular curriculum of preliminary, premedical medical, and hospital years of training after which he took a position with a steamship company at a small salary so as to lay by a moderate reserve to tide him over the lean years of early practice. The young man was naturally worried about his prospects and felt inclined to regret that he had undertaken the study of medicine.

Knowing him to be a reliable and fairly successful student I was at a loss to account for his attitude until he informed me that an acquaintance of his who had little or no advantage in the way of preliminary education and who had been employed at ordinary manual labor until about one year ago when, after a few months' course, he began prac-

tising as a chiropractor. To-day this man's income averages over $650 a month and our young representative of modern medicine feels keenly that there is "Something rotten in the state of Denmark," though where the rottenness begins is a question too deep for his page-crammed and otherwise preoccupied mind. By a strange coincidence on the very same day that this young man consulted me a young society matron informed me of an accident that had happened to one of her summer home neighbors. It appeared that my patient's friend had sustained severe injuries as the result of a fall from a horse and had been unconscious, so the story goes, for some hours. After the accident some one suggested calling in a regular practitioner but friends intervened saying, "A regular doctor will do nothing for her but ask questions and say when to expect him back. Get an osteopath."

Such is the condition of affairs that confronts the young medical man of to-day starting out to practice according to the traditions of the regular profession; and it is quite pertinent for him to ask us his seniors in the profession, and more especially his teachers in the medical schools and hospitals, what steps, if any, we have taken, or have under consideration, to protect the young practitioner or at least to equip him so that the struggle of his earlier years in the practice of scientific medicine may not be a painful and ignominious one against hopeless odds. The answer, if one has to be given to such a question here, is that no steps have been taken and none is under consideration which can materially aid our younger colleagues whom we yearly or quarterly toss into the maelstrom of competition with scientifically unencumbered rivals and then, with callous disregard, abandon to their fate. Not the least important result of such abandonment by their elders in the profession has been a tendency among the younger practitioners to commercialize their calling at the expense of the time-honored ethical traditions. This statement may painfully surprise many among the laity who, deep in their hearts, still admire the regular profession but perhaps it is just as well to remind these favorably disposed individuals that admiration alone will not sustain a profession whose lofty altruistic ideals are heavily counterbalanced with numerous earthly needs.

To appreciate its full significance the problem of medical practice must be squarely investigated from the standpoint of the laity as well as of the professional man thoroughly conversant with the technical aspect of the question. On the part of the laity it is often asserted that patients seek outside aid only after they have found that the physician practising in the regular way "did them no good." Many of these individuals insist that all the regular doctor ever does for them is take their name and address, ask a few questions about the family and personal history, and then "prescribe pills" after which he politely shows them the door telling them to report on a certain date. Others complain that the doctor never tells the patient anything about himself; that when he comes to the doctor's office with what seems to him to be merely a slight trouble of no significance, the man of science, grave in manner and tone, gives him to understand that his condition may be serious but professes to be powerless to diagnose the case until he has had an *x*-ray and half a dozen other laboratory reports. In the meantime agonies untold must be endured as a result of the suspense created by the doctor's all too conscientious attitude toward the patient and his illness. Is it any wonder that these patients who, for the most part belong to the class suffering from functional as opposed to organic disorders, rush for solace from their fears of what may be the matter with them to the "practitioner" of whatever system who with a standardized pigeon-hole diagnosis gives them immediate and positive assurance that he can cure them? These patients are very human. What they need at the moment is a little human help in the way of sympathetic understanding and assurance and these they get cheerfully and without delay, from almost any kind of a quack but not from your modern up-to-date physician who for the most part is too wrapt in the distant prospect of laboratory findings to sense the needs of the agonized human being sitting at his elbow. In the light of these facts, for facts of not infrequent occurrence they unfortunately are, the attitude of the individual of average enlightenment towards the medical profession is likely to be one prompted by the dictates of self interest rather than by those of reason and far-seeing justice. The patient who has obtained relief from his sufferings after treatment by an outside healer naturally feels grateful beyond bounds towards one whom he regards as his benefactor and savior. The average individual in this state of mind is beyond argument and reason. His side of the question, which to him seems to be the only side, he states clearly and with all the outward appearance of conviction and finality, as follows: "Well, he helped *me* and it makes little difference to me and my family under what system he practises. The proof the pudding is in the eating, and there you are."

This kind of argument is heard so frequently of late that it will repay the reader if we examine it at some length. In the first place, assuming that the outside healer actually did help the patient, it might be asked: By virtue of what kind of ministration did he help the patient? Was the patient benefited because of the peculiar system under which the healer practised, or was it because of something altogether extraneous to the system? The patient may insist that the point here raised does not concern him. But is this true? If it can be shown that similar results in similar cases can be and are obtained by different forms of treatment given by healers practising under widely different systems some of which sanction physical means whilst others sanction purely mental means (suggestion), what becomes of the claims of certain classes of healers to legal recognition on the strength of practising a "scientific system of therapy" which on the most superficial investigation discloses itself to be not only unscientific as dispensing actually, if not nominally, with the necessity of diagnosis but wholly unnecessary and superfluous since the results obtained by its practitioners bear no essential relation to the system of practice and can be obtained in many other ways independently of the system? If these things be so, and they have all the outward and inward signs of truth, how are we to fix the *moral status* of the

healer who, for instance, makes a snap diagnosis of "gall-bladder trouble" in a woman suffering from a manually palpable sarcoma of the kidney and proceeds to treat her by massage which tends to disseminate the disease throughout the body and hasten death? or of the "practitioner" who, after a ready made diagnosis of "trouble resulting from a dislocated cervical vertebra" proceeded to reduce a dislocation which had no existence in fact in a patient who all this time was suffering from epidemic encephalitis and who later on died in the hospital from this disease? If argument along these lines does not appeal to the individual sufferer who seeks relief at any cost it may be pertinent to ask that better informed portion of the community consisting of persons of culture who feel themselves constrained to advise supposedly less well informed sufferers to take treatment from some special exponent of this or that particular system, how they manage to evade the *moral issue* involved in recommending charlatans inside or outside the profession, who either lie directly and wilfully, *e.g.* in the matter of diagnosis, or manifest such a reckless disregard for truth that constructive intent to deceive becomes an inevitable implication. A further question that might be put to these cultured guides of suffering humanity is: Do you mean by your patronage of unscientific systems of therapy to disavow all attempts at healing based on scientific principles, and, if not, where are you, and the public at large, going to find a supply of scientifically trained medical men to care for you to-morrow when you wake up to the reality of your present folly? The fallacy under which the laity labors and especially all those who believe they have been benefited by various kinds of "practitioners" closely resembles the well known fallacy of *inference by added determinants* which is fairly exemplified in the two following examples: (1) A cottage is a house; therefore a *large cottage* is a *large house.* (2) A dwarf is a man; therefore a *large dwarf* is a *large man.* The fact that Silas Brown, having found a tender area on the spine of a neurotic patient, even as did Hippocrates two thousand years ago, lied to the patient in saying that a "dislocated vertebra" or a "maladjusted spine" was the cause of the tenderness and of the rest of the patient's ailments; and having so lied, proceeded to remove this fictitious cause of the patient's troubles by a pretended reduction of the supposedly dislocated vertebra or maladjusted spine, does not prove, even in the event that the patient felt benefited after the treatment, that the *system* under which Silas Brown "trained" and "practised" was a scientific system of therapy any more than it proves that such a system is universally applicable without regard to the nature of the ailment or possible damage to the patient. In fact it proves nothing at all as regards the scientific merits or shortcomings of the system. All it proves strictly is that somehow or other the patient was benefited *after* though not necessarily *because of* the particular form of treatment avowedly administered by Silas Brown just as many neurotics in similar circumstances are benefited by the fantastic philtrums and potions prescribed or dispensed by fortune tellers and others. To the wary and open-eyed it proves that treatment not based on scientific diagnosis may, by some happy chance, be actually followed by improvement instead of disaster. The writer wonders if the cultured few, who seem to have hitherto overlooked the moral untenability of their position, having read what is here written, will open their eyes and adjust their conduct in accordance with truth and reason; or put down their heads and plunge forward in response to their baser, instinctive urges of self-interest or wounded pride.

Looking at the problem from the standpoint of one who not only has an abiding faith in scientific medicine and in its mission, but who from years of experience both as teacher and pracititioner, has had abundant opportunity to study the question from the *inside,* it would seem to be nothing short of foolish to attempt to deny that in one broad section of the field of therapy the profession has utterly failed to give adequate service to the ailing public. In the old days, before the impersonal laboratory machine had completely superseded the humane factor in practice, the needs of the multitude suffering from minor mental and nervous disorders were in great measure met by the sympathetic ministrations of the kindly family doctor to whom these sufferers, overflowing with faith and expectancy, came as to their friend and deliverer. But all that has been changed since the advent of routine laboratory diagnosis; and now, what with fear of the cost of laboratory reports and of drugs, etc., not to mention the oftentimes insignificant therapeutic results, the average person prefers to take his chances with any kind of irregular healer sooner than risk a visit to the representative of modern impersonal therapy. This failure of the profession to minister to the wants of those suffering from nervous and mental disorders is nothing new. Witness the scene between Macbeth and his physician (Act V sc. iii):

Macbeth. Canst thou not minister to a mind diseas'd,
Pluck from the memory a rooted sorrow,
Raze out the written troubles of the brain,
And with some sweet oblivious antidote
Cleanse the stuff'd bosom of that perilous stuff,
Which weighs upon the heart?
Doctor. Therein the patient must minister unto himself.
Macbeth. Throw physic to the dogs; I'll none of it.

This colloquy pithily states the problem as it presented itself to both physician and layman in Shakespeare's time; and Macbeth's reply to the confessed helplessness of the physician represents fairly the position the profession of medicine, wherever it proves inadequate, holds to-day in the public esteem. It will be urged, and with justice, that scientific medicine has made great progress in recent years, that in fact matters have changed considerably since Shakespeare's day; but from the standpoint of the laity the change seems to have been in many directions for the worse. This is the only hypothesis in view to account for legislation, already enacted in several States, and all but enacted in many other States, placing healers, who practise in the name of so-called scientific systems, and whose preparatory training is a joke from the scientific point of view, upon practically an equal

footing with the regular practitioner of medicine who has spent from ten to fifteen years of arduous preparation before being admitted to practice. Judging by the popularity into which these outside healers have come in recent years it would seem that the contempt of the laity for the regular profession has become, if anything, more acute and more generalized than it was in Shakespeare's time. And the reason for this, for it has a reason and a sufficient one, rests on the actual inadequacy of the profession to meet the needs of the ailing public. This last statement is a bitter pill for those of us who believe in scientific medicine, but making faces will not help us any more than making trips to Albany to secure the Governor's veto of bills that have already passed both houses of the legislature. It would be more to the point if we stopped for a moment linking ourselves optimistically with the achievements of modern science—realities though these be, yet realities it must be confessed that as yet have not found general application for the relief of the suffering masses—and tried to study the situation from the point of view of the neglected public. As men imbued with the spirit of truth let us face the situation, intolerably disagreeable as it is, and applying the methods of that science in whose name we practise let us proceed to an investigation of the low estate into which our honorable profession has fallen, in one direction at least, in the eyes of the laity.

Causes of the Profession's Failure.—We have already stated that with the advent of laboratory diagnosis the human factor in practice waned. The newer methods of examination had a tendency to focus the practitioner's attention upon this or that particular organ, that might happen to be diseased or suspected, leaving out of consideration or at all events very much in the background, the general effects which the illness might register as a whole in the patient's personality. It is here precisely that the modern practitioner has ignominiously failed where his otherwise incompetent rival has met with a considerable degree of success. It seems incredible, in the light of the great advances that have been made in the elucidation of the mechanisms involved in both mental and physical disorders, as well as in physical and mental therapy, that the regularly trained physician after his years of study and experience in the medical school and hospital should have any serious rival in the esteem of the public. This anomalous situation is to be explained only by the fact that our teachers, and more particularly those responsible for the teaching curricula in our medical schools and hospitals, seem to have overlooked one of the main objects of medicine which is the *relief of human suffering*. The fact that up to quite recently neurology was rated as a *secondary subject* in our medical schools shows clearly in what esteem those responsible for our teaching curricula held neurology, and perhaps even now reflects the lethargic attitude of the bodies governing medical education, and of the profession in general, towards a problem, neglect of which has already undermined the foundations of our higher standards of medical education to such an extent that the very existence of the scientific medicine of our fathers is threatened. The failure of the profession is the immediate consequence of our failure to give the students in our medical schools and hospitals proper practical instruction in neurology and the allied subjects, psychiatry and psychotherapy. Without adequate instruction in these subjects the young practitioner is not only not able to diagnose or treat properly the ninety per cent. or more of all his cases that seek relief from ailments the genesis of which lies ninety per cent. or over within the psychic domain; but he is blissfully unaware of what scientific therapy has to offer for the relief of such cases and he continues to mistreat them until the unfortunate sufferers are driven in desperation to seek help elsewhere outside the ranks of the regular profession. The profession has as yet never been in a position to offer the public in an organized, systematic manner such service as science has long ago placed at its disposal for the benefit of those afflicted with mild nervous and mental disorders because such organized service can never be realized until a much closer affiliation than as yet exists, has been effected between the medical school and the hospital and between the hospital and the general practitioner on the firing line.

But a cause deeper lying than any yet mentioned stands behind the failure of the profession and that is the materialistic conception of life with which medical men have, more or less unconsciously, become imbued, to the detriment of their own efficiency as practitioners, from contact with those who regard the laboratory and the method of the laboratory as the sum and measure of all truth. Within its proper sphere of application, *i.e.* in the *natural sciences*, the laboratory method or the method of induction is perhaps indispensable; but this method can by no means replace either the deductive method which is the method of mathematics or the introspective method which is the method used in all psychological investigations properly so called. The mechanistic hypothesis in which all vital manifestations are regarded as the outcome of the physicochemical properties of matter has long ago been discarded as inadequate even by those supposedly representing the advance guard of modern European thought. Only laboratory scientists, with some notable exceptions such as Haldane the Oxford physiologist and a few others, have clung to this fetich of an outworn fallacy; but the unfortunate part of it is that the teachers of our medical students have blindly accepted the misapplied, erroneously extended method of the laboratory and continue to exploit the materialistic conception of man's nature and of his ailments to the infinite detriment of the profession and of the ailing public. With a rigid insistence on the part of their teachers upon the materialistic conception of disease it is no wonder that the regular practitioners of medicine turned out yearly by our medical schools practically confine their efforts to physical methods of therapy to the exclusion of psychic methods. This is one of the first fruits of the blind acceptance by the teachers of medicine of the mechanistic philosophy of laboratory scientists, viz., the restriction of the regular practitioner of medicine to the employment of but *one arm*—the physical one—of the therapeutic service to the exclusion of the psychic arm, although this latter, because of its wider sphere of application, if for no other reason, is, in the majority of

ordinary ailments, perhaps the more important of the two. In the practice of to-day each of these arms is entitled to its place and in any given case of illness each has its indications and cannot be supplanted by the other. All illness has its mental as well as its physical aspect and the properly trained physician should be ready to avail himself of every legitimate means to help his patient. As the aim of scientific medicine is not confined to the prevention and cure of disease but extends also to the relief of human suffering, so the ministrations of the practitioner are not necessarily at an end when physical remedies fail. There still remains the psychic arm with the ever present possibility of human fallibility. The most pathetic not to say tragic figure imaginable is that of the physician who with the best of intentions has given up a case as incurable which through ignorance or oversight he has incorrectly diagnosed. Patients rashly and prematurely condemned in this manner to death or hopeless torture are not likely to think kindly of the doctor or of his profession; nor are they likely to prove amiable in argument. If we regular practitioners of medicine could but see ourselves as others see us trying with the aid of our laboratory reports and pill boxes and even our scalpels, with none of which is there ground for complaint when used in their proper places, trying to

"Pluck from the memory a rooted sorrow,"
or to
"Raze out the written troubles of the brain,"

we would begin to understand why it is that the public who have in vain long and anxiously knocked at our doors, have turned from us and have wandered into the wilderness where, under the ægis of legislative sanction they burn incense at the altars of strange divinities.

Solution of the Problem.—Is there a remedy for the situation? There is, but it does not consist in legislation prohibiting our rivals for popular favor from practising. Nor does it consist in legislation prescribing courses of study in our medical schools and the infliction of penalties upon schools that for the moment find themselves unable to comply with the *letter* no matter how well they live up to the *spirit* of the law. The real remedy for the situation is to put the regular profession in a position to meet the needs of the ailing public in a systematic organized manner. The first step towards such organized service should be the establishment, in every general hospital throughout the country, of an independent neurological service under the supervision of an attending neurologist who should be allowed to have three or more adjunct attending neurologists serving under him. Under the present system the position of the neurologist upon the hospital staff is that of consultant. This means that in so far as the deliberations of the medical staff are concerned the neurologist is a mere outsider which, in view of the advantage to be derived from group diagnosis and treatment, is a distinct loss not only to the neurologist and the members of the medical board but also to all those afflicted with nervous and mental disorders who seek hospital aid. With the establishment in each general hospital throughout the land of a neurological service on equal footing with the medical and surgical services, the next step would be to organize the service so that patients suffering from mild nervous and mental disorders may have, from the outset, the benefits of scientific treatment such as is possible only in the hospital with its specially trained nursing, social service, and other staffs. The establishment of such an organized neurological service in our general hospitals would come as a great relief to the general practitioner and neurologist alike who, under present conditions, are often at their wits end to know just what to do with psychoneurotic patients brought to them in the acute stages of their malady when such patients are not fit subjects for psychoanalysis and allied forms of treatment. Under ordinary circumstances many of these patients after a period of unsuccessful because inappropriate treatment find their way into the hands of outside healers under whose care the surface manifestations of the functional disability often disappear. As all such cases are made the most of in discrediting the profession when proper provision has been made for their scientific treatment in the general hospital where they can be seen daily by the attending neurologist or one of his adjuncts, an effective blow will at last have been dealt to the many irregular forms of therapeutic exploitation which at present menace the future of scientific medicine. The advantages of an independent neurological service in our general hospitals are numerous and of vital importance not only to the public welfare and to the hospital and all officially connected with it, but to the medical profession in general. It is only with the establishment of such a service that the practical teaching of scientific psychotherapy can ever become a reality. Let our medical schools and hospitals but give the public a few years output of young men properly trained in scientific psychotherapy and the regular profession will rapidly and deservedly rise again in popular favor. To the writer it seems absurd that the properly trained medical man should have, outside the ranks of the profession, any serious rival in the field of therapy; but if the teachers of medicine and more especially those responsible for the curricula in our medical schools and hospitals, after years of boisterous effort to obtain high standards of medical education must confess their inability to deal effectively with the situation, only one of two courses remains open to them in logical consistency, viz., to try other methods or to abandon all attempts to maintain high standards. What is the use of exacting years of preparation from our young men in the name of the public welfare when the public itself gives preference to rivals practising under systems that require no scientific training worthy of the name and dispense with the necessity of diagnosis? On the face of it the position of our medical educators is exceedingly bad as matters stand. But the position of the public in this important question is no better. Their pragmatic attitude in the matter is not only selfish but incredibly shortsighted. To-day they are satisfied with the flimsiest kind of empirical therapy offered by men of no scientific training; to-morrow, when the need arises, they will clamor for scientific help which will not be forthcoming. They tell us that whatever cures them satisfies them; that the test of a remedy is not whether it is well grounded on scientific principles but whether it "works."

Smug pragmatism such as this may sound reasonable enough to the bulk of the community with eyes only for their own needs of the moment; but for the man of culture with an eye for the future it carries cold comfort. If matters continue as they are it will soon not be a question of the public choosing between the scientifically trained men of the medical profession and the exploiters of pretendedly scientific systems of therapy. In a very short time only one class of therapeutics will be available for the masses who for long years to come will be compelled to take their chances with practitioners working in the dark, using the trial and error method, which may seem logical enough in desperate conditions where no other method offers any hope, but which in the ordinary run of cases amounts to little more than reckless gambling with life and health. In spite of appearances, however, in the author's opinion the position of the medical profession is not quite hopeless. The public, not without reason, have resented the blindly autocratic attitude of the regular practitioner, and taking the matter into their own hands have gone on a rampage of radical reform. Their attitude towards the profession just now is very similar to the avengeful attitude which labor the world over has taken towards capital and with similar disadvantages to themselves. As in the case of labor the solution of the problem cannot be worked out by labor alone without compensatory adjustment on the part of capital so this medical problem cannot be solved by the public frantically pulling against the profession. At a conservative estimate it may be admitted that of all the ailments for which relief is sought 90 per cent. or over, are self limited and tend to get well. It may also be admitted that in over 90 per cent. of all human ailments the psychic is the dominating factor. Taking these statements as approximately representing the facts in the case it would seem that the pressing need of the public is *doctors and more doctors ready and able to give this* 90 *per cent. or over of the ailing public, service* in the way of prompt diagnosis and treatment without subjecting every frightened unfortunate who comes with an insignificant toeache to the ordeal of examination by an interminable string of specialists and the intolerable burden of unnecessary laboratory fees. Nothing here stated should be construed as antagonistic to legitimate laboratory or consultation service. The routine infliction of such service upon a bewildered public where it is not at all indicated is quite another matter. Keen observers will have noted that the main support of outside healers comes, not from the very poor who cannot afford to pay specialists' and laboratory fees, but from the well-to-do who naturally resent the expense involved in a visit to the modern regular practitioner. It cannot be denied that outside healers have sprung up in response to the public demand. What is significant in their daily growing numbers is the fact that they are becoming legalized in one State after another and are already clamoring at our hospital doors for the right to practise upon equal footing with the regular practitioner of medicine. Something here for medical economists to consider: for in a very short time, if matters continue as they are, the regular profession in spite of its highly vaunted educational standards will be absorbed by its more practical if less sophisticated rivals. Two facts should be stressed here for the benefit of the profession. One is that the position of the public is not without grounds for justification and the other is that the public, although at present in a fury of resentment against the regular profession, have not as yet completely lost their heads. At heart they are still true to the profession and if the latter has sense enough to come down off its high horse and offer service such as only the regular profession, when properly organized, has in its gift to offer, it will soon become apparent that, when given the chance to distinguish between them, the public still knows the difference between real gems, even though they be a little off color and marred by numerous flaws, and the glittering rhinestones which for the moment seem to have captivated the popular fancy. The need of the hour is a constructive policy as outlined above. Whoever takes the initiative in adopting such a policy and putting it into practice will prove himself a real benefactor not only of the ancient and honorable profession of medicine but of humanity at large.

HEMANGIOMA AND LYMPHANGIOMA, THEIR RESPONSE TO THE INJECTION OF BOILING WATER.

By FRANCIS REDER, M.D.,

ST. LOUIS.

A HEMANGIOMA is a tumor composed of an abnormal formation of blood vessels produced from a matrix of angioblasts. A lymphangioma is a tumor composed of an abnormal formation of lymph vessels also produced from a matrix of angioblasts. These tumors are congenital in their origin and clinically are considered non-malignant, although their histological formation closely resembles that of certain types of malignancy.

Angioma and lymphangioma are closely allied to endothelioma, their cellular elements lining the walls of the vascular spaces possessing the shape and arrangement of the mother soil.

In differentiating a vascular tumor of an angiomatous nature from a varicose vein or an aneurysm, the character of the formation must be taken into consideration. The growth of a normal blood vessel is furnished by the angioblasts. It is the essential tissue element. When such a blood vessel has reached its requisite normal size, the process becomes stationary.

In the development of an angioma there is no limitation, and the function of the angioblasts and their product of tissue proliferation results in the formation of atypical blood vessels, which constitute the essential tumor tissue of a hemangioma.

The growth of an angioma is governed by the formation of new blood spaces coalescing with existing older blood spaces. When the tissue proliferation is a rapid one, the tumor grows correspondingly in size.

In a varicose vessel or an aneurysm, such a process of proliferation does not take place, the size and form of the tumor being caused by a weakening of the wall, the result of disease. The differentiation of a lymphangioma from elephantiasis arabum is

borne out on similar lines. New vessels are formed by angioblasts in the walls of preexisting lymph spaces by a process of budding. These new lymphatic channels coalesce and communciate with the older lymph channels, the process extending to places where, in normal conditions, no lymphatics are found. In elephantiasis arabum the lymphatic enlargement is a dilatation of a diseased preexisting vessel.

On an anatomic basis hemangiomata and lymphangiomata can be classified into three species: The capillary variety, the cavernous variety, and the plexiform variety of the angiomata and the cystic variety of the lymphangiomata.

The capillary variety of angiomata is the incipient form of vascular tumor. As a rule the tumor tissue does not extend beyond the subcutaneous cellular tissue. This form is of little clinical significance.

The cavernous variety has its seat in the deep connective tissue. Its formation presents a distinct tumor. This form is of much clinical importance.

The third variety of hemangiomata, the plexiform species, is very rare. It is also known as "aneurysm by anastomsis" or "circoid aneurysm." Such an angioma may consist of arteries only, or of veins, or of arteries and veins in equal proportion. When the arterial element predominates, a marked tortuosity of the vessels is apparent.

The cystic variety of lymphangiomata differs from the cavernous insofar that the individual separate spaces arising from new and dilated lymph channels possess forms which correspond with their origin. They are more or less globular in shape and more prone to a progressive growth. than the cavernous.

Hemangiomata and lymphangiomata have many fundamental points of structure in common, and a differentiation between them should present no difficulties. The content of the former is blood, that of the latter lymph. A hemangioma has a bluish discoloration and the tumor can be usually emptied of its content by gentle pressure. A lymphangioma is generally colorless. Occasionally the walls of a lymphatic cyst will harbor blood vessels which will impart to it a blue or pink discoloration. The contents of a lymphangiomata cannot be expressed, the tumor on account of its firmness and elasticity will however permit of a certain degree of compression.

Angiomata are met with more frequently than lymphangiomata. In my experience in a ratio of 15 of the former to 1 of the latter.

With this preamble concluded, let us consider the treatment of these vascular tumors with the injection of boiling water.

These neoplasms may develop in any part of the body, but the face seems to be the preferable region for the angiomata. It is therefore significant that any treatment instituted should invite the least amount of disfigurement through scar formation.

Of all surgical measures the ideal treatment is excision. This is the method of election, provided the tumor is favorably situated and the operation can be undertaken without the danger of great hemorrhage or the loss of important structures.

Excision of a vascular tumor situated in the face demands the most serious contemplation, and should be undertaken only when there is convincing evidence that other methods of a less radical nature are unsuited. Of the less radical measures the injection of boiling water is deserving of earnest consideration.

This measure was originated by Dr. John A. Wyeth. It possesses a distinct advantage over all other coagulating methods, especially the irritating injections of chemical substances, which possess little or no merit, and are often harmful. The object of the treatment is to destroy the growth with all its constituent elements by an interstitial action. Boiling water injected into a hemangioma or a lymphangioma will by coagulation convert the contents of the tumor into a compact mass, causing a vascular blockade by aseptic thrombosis. The subsequent course is a degenerative tissue metamorphosis of a granular or fatty nature, resulting in the gradual obliteration (partial or complete) of the tumor.

The injection of boiling water into a hemangioma has been a most encouraging procedure, the tumor invariably disappearing in from 4 weeks to 4 months, the time for obliteration being governed by the size and location of the tumor. About 200 hemangiomata have been subjected by me to this method of treatment, and the results have been very satisfactory. Some of these tumors were hopelessly inoperable.

When the results of the lymphangiomata injected with boiling water are reviewed, they contrast negatively with the good results obtained in hemangiomata.

It was noted that the injection of boiling water into a hemangioma was followed by very mild systemic disturbances, whereas the reaction in a lmyphangioma was often violent. In the series of 200 cases of hemangioma 5 became infected. These infected cases responded promptly to aseptic wound treatment.

In a series of 8 lymphangiomata injected with boiling water 2 became infected. The infections were undoubtedly of a hematogenous nature, in the one case resulting from a sore throat and in the other from an ulcerated tooth. These patients were seriously sick, the severest systemic disturbances lasting from 10 to 14 days. The parts involved (in one case the hand, in the other the foot) presented the clinical characteristics of a phlegmonous inflammation. There were present chills, with a temperature of 104° to 105°, delirium, and vomiting. The inflammatory condition did not result in suppuration in either case. Both patients recovered after a protracted convalescence.

The predisposition to infection of an injected lymphangioma must be ascribed to the low resisting power of the coagulated lymph. With an injected hemangioma such a predisposition does not seem to exist, presumably because blood being a tissue of high resisting power, bacterial invasion becomes more difficult. The response from the injection of boiling water in the 8 cases of lmyphangioma, although not as encouraging as the results achieved in the angiomata, was satisfactory.

It may be said that in two cases the tumor entirely disappeared. In the remaining six cases the tumor was reduced to about two-thirds its normal size. A second or third hot water injection, given in four instances, had little influence upon any further shrinkage of the tumor. In those cases where the lym-

phangioma involved the hand or the foot, together with some of the fingers and toes, the injection caused a marked decrease in the size of the hand or foot. The enlarged fingers or toes, however, were affected to only a small degree.

Although the response from an injected lymphangioma does not give the encouragement an injected hemangioma does, the measure of injecting a lymphangioma with boiling water is a most valuable asset, especially in those cases where an operative procedure is contraindicated and where intervention seems imperative.

THE PHARMACEUTICAL ASPECTS OF NATIONAL HEALTH INSURANCE.*

By FREDERICK L. HOFFMAN, LL.D.,

NEWARK, N. J.

THIRD VICE-PRESIDENT AND STATISTICIAN, THE PRUDENTIAL INSURANCE CO. OF AMERICA.

VERY briefly, the results of an extended investigation into the pharmaceutical aspects of National Health Insurance, may be summarized as follows:

The subject has heretofore received entirely inadequate public consideration, largely because of its very technical aspects affecting a single and rather isolated profession. Under National Health Insurance the Government assumed responsibility for the supply of the necessary medicines and surgical appliances in the case of insured persons, resulting in a so-called "panel system," under which druggists willing to do so supply medicines under special contractual conditions to insured persons on the basis of a script, furnished by the attending physician. The theoretical assumption, based upon very inadequate investigation was that on the average 1s. 6d. per insured person ought to be sufficient to provide drugs for the insured population. But it has been said that "In order that they might, as they ought, be absolutely safe, they added by way of reserve another 6d.—the floating 6d.—to which, or to the unexpended balance of which, the doctor has the reversionary right.

It must be self-evident that any such theoretical assumption of per capita cost would necessarily result in the adaptation of a governmental measure to the amount available for distribution, rather than that the adjustment would be in the direction of an adequate and proper supply of drugs for the insured population. It has also been said in this connection that "It is obvious that to fix a definite sum to meet an obligation which is indefinite in amount, is, after all, in accordance with the doctrine of average, upon which the whole principle of insurance is based." This would be perfectly sound, if it could be said with entire truth that insurance principles in the accepted sense of the term regulate the operation of National Health Insurance. This not only is not the case, but as said in an address on the drug fund, prepared by the Scottish Association of Insurance Committees, "The peculiarity in this instance is that after the regulations are framed the drug fund is kept free from liability in case of shortage and the risk is put upon the chemist who sells his goods and is bound to supply his goods on the order of the doctor—without the right of refusal, even though he may be of the opinion that the individual doctor is acting extravagantly."

These introductory remarks emphasize the numerous difficulties of drug administration under National Health Insurance, resulting during the present parliamentary session in the floating 6d. being done away with and, as far as I understand the present situation, in the assumption of the entire cost of medicines by the government. Overprescribing is the penalty of the physician who, aside from cases of sheer negligence, must frequently think more of his patient than of drug economy. But to avoid over-prescribing, an immense range of schedules, fees, and allowances has to be kept constantly in mind, a serious additional clerical task upon an often over-worked general practitioner.

A description of drug practice under the act presents a most interesting aspect of government interference in what heretofore has been almost exclusively a field of private enterprise. As observed in the report of the Association of Scottish Insurance Committees, "It is doubtful if there is to be found in any commercial dealings such an anomalous situation as we find here." The situation has been enormously complicated by making it to the personal interest of the doctor to practice economy in drug prescribing, in that the so-called floating 6d., or the difference between the 1s. 6d. definitely assigned and the 6d. additional indefinitely assigned to the drug fund, accrued to the benefit of the practitioners' fund and became available for distribution at the end of the year. There being the further complication of a very considerable rise in drug prices; of the impossibility of securing certain drugs at all; of the national importance of rigorous economy in prescribing for general reasons in consequence of the war, and the difficulties of securing adequate technically trained dispensing assistants. Before I proceed, it is necessary to point out a fact not generally known. It was the customary practice of English physicians previous to the passage of National Health Insurance to do their own dispensing, or compounding of medicine, as part of an inclusive fee. Under the law this practice is now practically prohibited, except in remote rural sections, and an immense amount of additional business has, therefore, been given to practising druggists, but upon the basis of a capitation fee, held to be totally inadequate in many cases. A second point to be kept in mind is that a different rule of practice prevails in Scotland than in England, and possibly Wales and Ireland, so that in this case, as in others, it is not correct to speak of the system as one of "National" Health Insurance.

A review of the numerous negotiations between the associated druggists or the pharmaceutical societies of England and Wales and Scotland on the one hand and of the government on the other, would be utterly impossible at the present time. The negotiations, unfortunately, are not as much a matter of public interest as the corresponding negotiations of the British Medical Association, and the facts are, therefore, not made a matter of general record. But from such documentary evidence as has been placed at my disposal, includ-

*Abstract of an address delivered before the Cleveland Academy of Medicine, August 18, 1920.

ing the reports of so-called Drug Pricing Committees, I do not hesitate to say that the system or the method has become of prior importance to the objective of providing articles and proper medicines to the insured population. The chemists are in much the same position as the doctors, in that the bills rendered are frequently not paid in full, but discounted on the basis of the drug allowances, from 1s. 6d. to 2s. per capita. Of course, there is much division of opinion and in some respects much good has resulted from a change which would not be necessary in this or in many other countries, in which doctors, by preference, do not do their own dispensing. A bureaucracy necessary to administer a drug fund with a first regard to public economy in matters involving millions of small transactions—running into many millions, when all the facts are taken into account—must needs assume gigantic proportions. The so-called Price Checking Bureaus came into existence as a matter of necessity and they fulfill, in many respects, a very useful public purpose. They are under-staffed and underpaid, since the function is but half understood by the public, interested rather in an adequate supply of medicine than in the attainment of the highest degree of economy in drug dispensing.

There is a further point, to which it is necessary to direct attention, and that is the prevailing practice in Great Britain to give the preference to stock medicines, rather than to prescriptions written out in conformity to the principles of therapeutics. Stock medicines are legally authorized in Great Britain; approved as to their composition by the Ministry of Health; and dispensed in large quantities, not because of a clear recognition that they are to the best interest of the patient, but because a considerable economy is effected in dispensing cost. Every Insurance Committee, therefore, has its own local pharmacopeia, in which are embodied local preferences or prejudices, differing frequently from other communities, making a standard pharmaceutical practice difficult, if not impossible. It is clearly recognized that the use of stock mixtures has been economical because of the reduced fee which is allowed in many areas, but the major underlying cause is the continued habit of drug-taking in England, forcibly expressed in "a minute consultation and a bottle of medicine."

Every prescription under the present system is, therefore, subjected to careful examination by persons experienced in drug-pricing and in most, if not all, areas the panel chemists no longer enter the prices themselves, but merely give the quantity of the drug dispensed and the name. Thus, at least thirty million prescriptions are priced, examined and subsequently tested and verified, or re-examined by sub-committees of the local pharmaceutical society. The prices charged are generally net, or the cost of the drugs wholesale, to which there is allowed to be added a dispensing fee, or a so-called establishment charge. The amount of clerical labor involved in these multitudinous operations is enormous and the resulting chances of errors and disputes or misunderstandings are considerable. It, however, may be said that it is the present rule, in England at least, that the ingredients are paid for at cost and that, in addition thereto, a fee of 3s. 5d. is given in respect of all compounded drugs, medicaments and preparations, a fee of 2d. in respect of all single drugs, and a cost of 33 per cent. is allowed in respect of specified appliances. In addition to these, there is a dispensing fee of approximately 3d., it being estimated that an actively employed pharmaceutical assistant can earn on this basis an average of about 3s. an hour. In other words, there is the same trade union standard as in the case of medical practitioners, whose services have also been rated by the hour, to arrive at a compromise agreement as to the capitation fee.

STATUS OF THE LUETIN TEST.

By LOUIS HANNAH, M.D.,

SYLVANIA, GA.

WHEN first deciding to employ the luetin test, I entertained high hopes of its efficiency in at least a worthy percentage of syphilitic cases, on account of the credence accorded it by writers of standard text-books and the claims of the originator of the test (based on experiments) as to its specificity and value when positive. However, my experience with this method of diagnosis—being careful of technique—has been utterly disappointing, and in this connection I wish to state some of the facts which might be of significance.

In the application of approximately one hundred luetin tests, in unselected cases, I at first observed a few apparently positive reactions in isolated instances. Later, however, having learned that antisyphilitic treatment (with special reference to mercury) intensified the reactions, I began to administer potassium iodide and mercury in all cases for two or three days prior to application of the tests. Becoming suspicious of the frequency of positive reactions, following the iodide and mercury treatment, I reported to Dr. Noguchi a series of 30 consecutive such instances—referring, however, to only the administration of mercury—and in reply he stated that certain investigators had observed these pseudo-reactions after the ingestion of potassium iodide. Noguchi, nevertheless, recognizes a distinction between the true and the false luetin reactions, in that the former seems more delayed. As to this point which he makes, I wish to say that from my relatively few observations I conclude that it is too nearly impossible to differentiate the true from the false lesions to make the test of any value, for the following reasons: all reactions after potassium iodide were progressive, and exhibited all the stages—papular, vesicular, and pustular, or so-called torpid type—ascribed to the specific test; the lesions after potassium iodide presented the typical copper-colored appearance of certain syphilides; all positive reactions without iodide or mercury appeared within 48 hours, though much less intense than the drug reactions.

Of the 100 cases referred to there were eleven which exhibited persistent lesions, following the test without iodide or mercury, that might be considered positive. Five of this number gave definite histories of lues, and none responded to antisyphilitic treatment. In a considerable number of other instances there were doubtful reactions in the

form of very small papules, which disappeared in from three to five days; so that positive responses to the test would seem to occur frequently as the result of nonspecific sensitization by the injected protein. Possibly the demarkation between the specific luetin and the traumatic or other inflammatory reactions might be more apparent and easily recognized if the virus were applied through an abrasion of the skin instead of by the intradermic method. I add this suggestion for the reason that in my experience with the tuberculin test I found that the cutaneous method, with its control, is clear-cut and dependable, whereas I have never elicited a positive response, even in known cases of tuberculosis, by intracutaneous injection of tuberculin. Possibly, also, other preparations of the luetic extract, besides the one now in use, might perfect the luetin test, as in applying Old Tuberculin Human, O. T. Bovine, Bouillon Filtrate Human, and B. F. Bovine, a positive reaction often occurs from the filtrate, while the Old Tuberculin remains negative, when applied to the same individual and at the same time.

Since potassium iodide had previously always been administered in combination with mercury, in order to determine whether or not mercury produced reactions similar to those of the iodide I applied the luetin test to ten apparently normal individuals, with negative results in nine cases and a slightly positive reaction in one after forty-eight hours. On the fourth day, before defervescence of the true luetin reaction would have occurred, bichloride of mercury was administered and continued for four days. Results in all cases, after two weeks' observation, were negative; neither was the positive test intensified. It is well also to state that I have seen a number of reactions to the potassium iodide when given several days after applying the luetin, so that the delay in giving mercury could not have accounted for its failure to provoke reactions. In a later experiment on six of the above individuals, positive results were attained after the ingestion of potassium iodide. From these experiments I assumed that the drug reactions were due solely to the iodide.

In conclusion, I wish to say that having seen no reports in the current literature on the records of the luetin test, whereby its standard of efficiency might be established, my impression is that, unless the medical world or proper authorities are in accord with the status assigned to the test, it should be eliminated from standard text books—until perfected—as one of the methods for the diagnosis of syphilis. It is far from my purpose to discredit the efforts in this particular investigation of as eminent an authority as Noguchi, but I do consider that the profession should be spared the expense and disappointment of employing a method of diagnosis that is uncertain and misleading. It would be worth while to know what conclusions others have reached in regard to the luetin test.

Fixation Abscess in the Treatment of Lethargic Encephalitis.—Netter has treated a series of nineteen patients having this malady with artificial turpentine abscess and has lost but two patients. The author has now seen personally seventy-eight cases, and bearing in mind that the mild ease at onset may end fatally, he would test the turpentine abscess in all cases.—*Gazette des Hôpitaux.*

Medicolegal Notes.

Right of Hospital to Refuse to Allow Physician of Another School to Practise Therein.—In an action by a physician to enjoin members of a hospital staff and the hospital from preventing him from practising medicine in the hospital, the Texas Court of Civil Appeals holds that a voluntary association has the power to enact laws governing the admission of members and to prescribe the necessary qualification for membership. Membership therein is a privilege which the society may accord or withhold at its pleasure, with which a court of equity will not interfere, even though the arbitrary rejection of the candidate may prejudice his material interest. Courts sometimes interfere where members have been wrongfully excluded or expelled, but as a rule they do not interfere with the right of an association to make laws or rules unless they are against good morals or violate the laws of the State. The court considers such a society as the Potter County Medical Association, of which the defendants are members, is legitimate and lawful. If it is an organization which is largely composed of the defendant doctors, and if it does directly or indirectly affect the plaintiff's material interest or in some degree affect him as a nonmember, this would not justify the courts in denouncing it as an illegal or unlawful conspiracy. The association has the right to advance its purpose or interest and that of its members by all legitimate means. If it deemed the plaintiff an osteopath, and that as such he was supporting an exclusive system, the association and its members were within their rights, under its rules, in rejecting him as a member. They also had the right to refuse to assist him in operations. They could, if they deemed it to the interest of medicine or surgery, or the welfare of humanity, agree among themselves not to assist him in surgery if they did so in good faith and with no intent to injure him. To compel them to receive him into fellowship and accept his view would be to impose his will upon them and to force the medical world to accept his theory of the healing art. Courts have no such power. The plaintiff has an equal right to ignore the defendants'theories and practice as they have his. Each has selected his school of practice, and neither has the right to impose upon the other his peculiar views, but each is free to choose his own and follow the methods believed by them to be the wisest and best. Having so elected, there could be no just ground of complaint that in the competition of these schools and as resultant therefrom loss of material interest is sustained or professional reputation suffers or is eclipsed. If without malice or evil intent the defendants did interfere with the plaintiff's privilege, if they did so serve some legitimate right or interest of their own, they could do such acts themselves or cause others to do them so long as no definite legal right of the plaintiff was violated. A rule by the defendant doctors that there should be present at least three physicians at a major operation was held not to affect the plaintiff. He was not a party to the rule; he was under no legal or moral obligation to observe it. The court did not think the State statute of 1907, creating a board of medical examiners, defining medicine, etc., was designed to force one system of medicine to recognize all other systems as equal to its own, or to force it to affiliate with or accept members from other systems into its association under a penalty of mandamus, injunction, or damages, on the ground of discrimination. It holds that the governing body of a hospital may refuse to permit physicians professing a certain system of medicine to practise in the hospital and adopt such regulations as are proper or deemed by it necessary or expedient to improve the hospital, and require of those using its equipment that they possess specific medical learning and equipment in order to receive a membership on the medical staff. To accomplish this it was at liberty to employ a committee, as it did in this case, to standardize the sanitarium. If in good faith, with no evil intent to injure or oppress, the doctors who were so appointed did formulate the rules of standardization and name the staff as directed, they had the right to do so subject to no other control than the governing authorities of the institution.—Harris v. Thomas (Tex.), 217 S. W. 1069.

MEDICAL RECORD.

New York, September 25, 1920.

THE SITE AND NUMBER OF DUODENAL ULCERS.

AUTOPSY records and operation reports show that duodenal ulcer is usually single. Collin's statistics, comprising two hundred and thirty-three cases, including ulcers located on the four portions of the duodenum, give the following results: There was a single ulcer in one hundred and ninety-five cases, two ulcers in twenty-six, in three cases there were three, in four cases four, and in five cases there were five or more. Therefore, duodenal ulcer is a single lesion in 83.6 per cent. of cases according to Collin. The statistics of American surgeons show that a single ulcer exists in 95 per cent. of the cases, and in those compiled by Ricard and Panchet in France, from 80 per cent. to 90 per cent. These figures have not, however, an absolute value. Seventeen cases collected in Hartmann's service, at Paris, by Houdard, show that in sixteen the ulcer was single, while in one there were two ulcers, one near the pylorus, the other in the third portion of the duodenum. The starting-point of the first ulcer, which later had invaded the pylorus was, it is true, not very exactly determined.

The coincidence of gastric and duodenal ulcers has now become an established fact, and many instances have been reported; there are forty-eight cases out of a total of one hundred and eighty-nine cases of duodenal ulcer reported by Moynihan, while the case referred to by Houdard is, perhaps, another example. Quite recently Petrem published fifteen cases of duodenal ulcer, all of which presented gastric ulcers as well. It is important to be aware of these facts, because they should oblige the surgeon to explore the duodenum even if a gastric or pyloric ulcer has been found which could account for the symptoms offered by the patient.

The site of the ulcer must be regarded from two points of view, namely, on the walls of the duodenum and the various segments of this organ. It is generally conceded that the majority of ulcers are seated in the first portion of the duodenum, on the first four centimeters to the right of the pylorus, Moynihan's statistics showing that this is so in 95 per cent. of the cases. In Collin's autopsy statistics—a total of 262 cases—242 times the ulcer was in the first portion, 14 times in the second, 3 in the third and 3 in the fourth. Perry and Shaw's autopsy statistics of 143 cases give 125 ulcers in the first portion, 16 in the second, and one each in the third and fourth portions. Therefore, by combining the above figures—a total of 405 cases—there are 367 in the first portion, 30 in the second, and 4 each in the third and fourth portions. Hartmann's statistics show 13 ulcers in the first portion, 3 in the second and 1 in the third. Therefore, the ulcer is seated beyond the first portion in quite a good proportion of cases, but it should be remarked that in the latter statistics only cases of ulcer distinctly duodenal are considered. What is important to recall is that a duodenal ulcer of the second, third and fourth portions may alone exist or coexist with another in the first portion, so that the entire duodenum should invariably be explored at operation, and that this obligation still holds even when the first portion appears normal. This eventually is unquestionably the most frequent. The situation of the ulcer in relation to the pylorus is rather variable. Collin's statistics are interesting because they are based on precise anatomical observation. They show that out of a total of 242 cases of ulcer in the first observation 2 were astraddle on the pylorus, 4 encroached upon the pylorus, 74 were tangential to it, while 162 were situated from two to four centimeters from the pylorus. Therefore, about 33 per cent. were intimately related to the pylorus. Codman has also found duodenal ulcers in this situation and he insists on this type met with occasionally and which may escape notice if the examination is not carefully made.

The difficulty of making an exact localization of the seat of the ulcer by external examination at operation is well known and it has been quite conclusively shown that the pyloric vein is not a landmark of any precision in locating the ulcer.

The seat of the ulcer in relation to the walls should be considered, and Collin's statistics will again give more exact data than those obtained by rapid examination at operation, often rendered difficult by adhesions. When the site has been noted we find, for ulcers of the first portion, 68 were on the anterior wall, 3 on the anterosuperior, 39 on the posterior, 2 posteroinferior, 6 posterosuperior, 10 on the upper border and 1 on the lower border. In ulcer of the second portion 3 were on the internal wall, 2 on the posterior, and 1 on the external wall. In those of the third portion the site was noted in only 1, and this was on the anterosuperior wall. In those of the fourth portion 2 were on the anterosuperior and 1 on the posterosuperior wall. Therefore, ulcers of the first portion are usually seated in front and are visible at examination of the region, but it must be recalled that those seated on the posterior wall are far from being exceptional, so that the entire duodenum should invariably be explored.

It may, perhaps, be logical to admit that the reason that duodenal ulcer is more prone to occur in the first portion is because the mucosa is here in contact with acid chyme which the biliary and pancreatic secretions have not yet neutralized. The

first portion also comes up in front of the pylorus and the gastric contents directly surge against it each time the sphincter opens, so that the anterior wall is more directly acted upon and is the more common site of ulcer.

REPUGNANCE TO MEAT IN CANCER OF THE STOMACH.

SAVIGNAC discusses this subject at length in the *Journal de Médecine* de Paris for Aug. 5, 1920, xxxix, 15. He insists that a repugnance to meat occurs early in the history of the case and is of diagnostic value. But classic writers on cancer of the stomach do not, strange to say, mention this behavior. The repugnance is specific and does not, at least early in the disease, extend to other articles of food. In eliciting the information one should never ask a leading question about the appetite for meat, but the patient should be given every opportunity to answer the question in his own way. He may, for example, be asked what kinds of food he mostly craves or enjoys, and a number of ordinary articles of diet should be enumerated for him to select from. If a meal consisting of beefsteak and potatoes, an egg, a glass of milk, and preserved fruit is suggested, he will be pretty sure to say that he dislikes meat. But great tact is necessary to bring out the fact of specific disgust, for the patient may have a general repugnance to all food or he may be a vegetarian from choice. True repugnance can be predicated only when the subject, having taken a morsel of meat into his mouth, spits it out either at once or when, having masticated it, he is unable to swallow it. This reaction must be permanent and not transitory. Needless to say the meat must have been properly prepared and be acceptable to the average man. The cancer subject having acquired this repugnance to meat never regains his tolerance. While there may be repugnance to any kind of meat it is often limited to red meats, while tolerating fish and chicken. The dislike referred to does not in any way depend on dysphagia or the fear of swallowing a bolus of meat.

It being granted that this peculiar disgust for meat is present, how may the feeling be explained? In cancer of the esophagus the author has seen a good appetite and even a liking for meats. As a rule in serious affections of the alimentary canal with disturbance of appetite there is no repugnance to meat unless there is refusal of all food, as in insanity and hysterical anorexia. Hence the great value of the symptom in differential diagnosis. Nevertheless there is much difficulty at first in differentiating cancer from nephritis and uremia in subjects who enter the office with pallor and complain of dietetic disorders. In any condition in which dry mouth and throat are due to lack of saliva a repugnance to meat may be due to inability to masticate and insalivate the food, and this condition the author has found common in the uremic and pre-uremic. The latter conditions may be excluded by the necessary blood and urinary tests. Generally speaking the cancer patient may show this repugnance while still in apparent health, before he has begun to show emaciation and pallor and gastric symptoms associated with involvement of the pylorus. The author states that in 95 per cent. of men who suddenly discover a permanent repugnance to meat one should strongly suspect with reason a beginning cancer of the stomach. There should, of course, be selection—the men should be of the cancer age so-called, etc. There is a minority that never presents this symptom, just as there is a minority that retains all the enjoyment of food and eats to excess if allowed. Apparently the cause is not in the stomach itself, for the symptom has been seen in all forms of cancer, in ulcerated and nonulcerated alike, and in all locations. The symptom which naturally suggests itself is achylia gastrica but according to the author this is not the cause, for he has found the disgust in cases in which the gastric juice was normally present and even in excess. The absorption of some product of the cancer hardly explains the condition, and we have only the hypothesis left of a specific biological reaction, perhaps a defense reaction.

THE COMPLETE EXTIRPATION OF THYROGLOSSAL CYSTS.

THYROGLOSSAL cysts are rather uncommon, yet it seems remarkable that only 31 such cases were found in 86,000 consecutive patients examined at the Mayo Clinic. In that series the cysts appeared at various ages from birth to 53 years, the majority being found in patients between the ages of 20 and 25 years. In 25 of these cases the cysts were in the midline of the neck near the hyoid bone. When these cysts are opened and drained, instead of being entirely dissected out, a persistent sinus remains or there is an intermittent filling and discharge at the cyst, except in the very rare cases where infection of the tract is followed by destruction of the secreting epithelium lining the cyst and thyroglossal duct. Ordinarily, infection follows simple drainage operations and a sinus persists for months or years or for life or until the entire secretory tract is extirpated by operation. In the series at the Mayo Clinic referred to by Sistrunk (*Annals of Surgery*, February, 1920) many of the patients had sinuses which had persisted for periods varying from six months to twenty-nine years.

It is evident that there is but one sure way to cure the condition, namely, complete excision of the cyst and of its prolongation, if one exists, up the thyroglossal duct to the foramen cecum at the base of the tongue. Fortunately, in many cases the upper portion of the tract is obliterated; yet the lumen of the duct is so small and often so hard to identify, particularly after infection of the cyst, that sometimes after the surgeon has removed a cyst in the hyoid region and has felt sure that there is no prolongation upwards, he is chagrined at the return of the patient some months later with a reformed cyst, showing that there was a minute lumen in the thyroglossal duct and that the lining cells were still actively secreting.

In view of the ever-present possibility of such a contingency, the thorough method of excision advocated by Sistrunk would seem justifiable in practically all cases. As he says, the majority of operations for the cure of thyroglossal cysts are unsuccessful unless the epithelium-lined tract running from the cyst to the foramen cecum is completely removed. As a rule, the cyst and the portion of the tract lying below the hyoid may be dissected out without difficulty, but above this the tract is usually so small and friable that it is broken off easily and consequently is difficult to remove. Hence, instead of attempting to isolate and remove the duct by itself, Sistrunk removes the duct with the tissues surrounding it for a distance about an eighth of an inch on all sides.

The operation which Sistrunk describes in detail presents too great difficulties for the relatively inexperienced operator, but such a man does an injustice to the patient in attempting any sort of an operation for thyroglossal cyst, since anything short of complete extirpation usually means recurrence and a much more difficult operation for the competent surgeon who ultimately gets these maltreated cases and has to begin his operation through a mass of scar tissue. Whatever the method, radical extirpation is work that requires an expert surgeon; and to him Sistrunk's method should appeal.

The Gastric Pouches in Biloculation of the Stomach.

The difference in size of the gastric pouches in bilocular stomach—a cause of many mistakes during the preradioscopic era of gastric surgery—is most usually dependent upon the narrowness of the stenosis, which provokes an enormous distention of the cardiac pouch, or upon the association of a pyloric stenosis with a midgastric lesion. The latter coincidence is rather frequent and the cases collected by Santy (Thèse de Lyons, 1915) in reference to excision show that in 15 per cent. of mediogastric stenoses pyloric narrowing was also present. Spannaus has met with this association much more frequently than Santy, because the thirty-four cases he reports from Küttner's clinic (*Beiträge zur klin. Chir.*, Bd. lxxv) include six of pyloric stenosis, otherwise 17 per cent. An extreme smallness of the cardiac pouch is, no matter what has been said to the contrary, relatively rare; it may be simulated by a pushing of the midgastric stenosis to the left side in instances where a marked dilatation of the pyloric pouch exists. The very high site of the ulcer near the cardia should theoretically result in high seated stenoses and small cardiac pouches. Realized to a certain extent in practice, this type of biloculation with an inaccessible upper segment is much more commonly the result of adhesions arising posteriorly to the pouch which, being thus fixed, cannot be drawn down. The fundus of the stomach is therefore only exceptionally the seat of the stenosis. Torsion of the pyloric pouch is a condition rather frequently encountered during operation. Sometimes the torsion of the pyloric segment—which revolves around the long axis of the stomach so that the greater curvature is uppermost—has only begun, in which case it simply contributes to exaggerate the signs of midgastric stenosis. On the contrary, at other times it assumes the character of a genuine complication, in which case the torsion is a complete one, realizing a true volvulus with accidents of occlusion likewise acting upon the loops of small intestine and transverse colon which are carried along with the movement of rotation. Such instances have been recorded by Boucart, Clément, Reinecke, and others. The torsion around a vertical axis passing through the stenosis has occurred in such a way that, the anterior surfaces of the two pouches coming in contact, a genuine anterior spur is formed projecting into the gastric cavity, thus exaggerating the effect of the stenosis. A classical example of this condition has been published by Saake.

The Voluntary Apneic Pause.

The literature of this subject is somewhat scattered and Professor Sabrazes has rendered a service in collecting numerous data for an article in his journal, the *Gazette hêbdomadaire des sciences médicales de Bordeaux* for June 20, 1920, xli, 25. He himself made a contribution to the subject in 1902 and by means of a split-second watch made the average interval 20 to 25 seconds, while 30 to 35 seconds is exceptional. Voluntary apnea is known to vary in different pathological states and in mitral insufficiency with asystole it does not exceed 5 to 10 seconds. It is understood that in these tests there is no preliminary forced inspiration, for apnea under these circumstances has its own laws. In mitral insufficiency after compensation has been reestablished by digitalis, the interval is slightly prolonged—from 10 to 15 seconds. It is of interest to note that in pulmonary tuberculosis, even if advanced, the interval is not notably shortened. The author announced in his early paper that the blood pressure rises during the apneic pause, and that the oscillations of the head (so-called sign of Musset) may appear or become more noticeable during the pause. In the study of miscellaneous individuals the breath is not always completely held and a slight amount of respiration then persists. Again the subject may take a deeper inspiration than normal before holding his breath: in such cases the test is vitiated and the interval may be 40 to 50 seconds. Quite recently Binet and Bourgeois have written on this subject and mention only intervals following deep inspiration. They place the average interval at 50 seconds. In aviation tests subjects whose pause is 45 seconds or less were deemed unsuited for respiration in high altitudes. Other data are given, but the author does not allude to the relations of voluntary apnea to tolerance of anesthesia nor to the long intervals seen in special individuals such as divers.

Progress in Cryotherapy.

In a summary of this subject by Lortat-Jacob in the electroradiological and physiotherapeutical number of *La Médecine*, June, 1920, i, 9, credit is given to various Americans for the introduction of refrigeration, liquid air, and carbonic acid snow into dermatology. The French have not been idle. Sa-

bouraud, Paytrier, and the author have used the snow freely in practice, while Bordas and Béclère have devised apparatus for application of this substance, as have also the author and Vitry in common. In addition to the dermatologists some of the surgeons have applied the snow to cases of lupus erythematosus. Delbet has been able to collect notes of 80 cases of this malady thus treated, going back as far as 1907. Of this number 12 patients were lost sight of, and one is still under treatment. Of 67 others 26 were completely cured and 36 much improved, while 4 have had relapses and but one was a total failure. Since Delbet's paper Mathias has reported 7 other cases with one cure, 2 improvements, 2 failures, and 2 patients still under treatment. At the Finsen Institute at Copenhagen the use of the Finsen light for this malady has been totally abandoned for cryotherapy. Della Favera has reported 10 cases of erythematous lupus treated by the snow and every one completely cured, and Le Bris also reports excellent results. As for lupus vulgaris, a few cures have been reported by Zeisler, Delbet, Marcou, and others, including the author. Superficial epithelioma has been cured by Zeisler, Martin, Nobl, Della Favera, Marcou, Mathias, and the author. Various kinds of nævus and angioma have often been reported as cured by this resource, and while some of these are small others are extensive. The author removed a large port wine mark occupying the half of the face in eleven sessions of 30 seconds each, and Bernay an angioma the size of a mandarin orange. In keloids and scar keloid the snow is the remedy of choice. Good results have also followed its use in tattoo marks, chloasma, freckles, xanthoma, and radiodermatitis.

Botulism or Lethargic Encephalitis.

De Rezende contributes an article with this title to the *Brazil-Medico* for June 5, 1920, xxxiv, 23. The patient presented a most unusual picture when first seen. He was at the time waiting on a physician in a restaurant and was seen to present ptosis. Asked about himself he complained of feeling ill and said he had double vision. He was advised to go home, but some delay resulted and it was not until three days later that he came under medical care. He then presented fever of 40° C. (140° F.) and delirium. This phase passed off and was succeeded by one of extreme prostration, accompanied by somnolence. Ptosis was still present, but diplopia seemed to have disappeared. The diagnosis at this period appeared clear—encephalitis lethargica. To register the peculiar physiognomy a photograph was taken and is reproduced in the journal. The subject improved in temperature and in his mental state. At this juncture Doctor Machado, who had been asked to see the patient, noted urticaria over the chest, which diffused itself over most of the surface and became more and more confluent. This phenomenon made the diagnosis somewhat doubtful and an attempt was made to exclude definitely certain other affections. The latest edition of the work of Purves Stewart on Diseases of the Nervous System (1920) specially calls attention to the remarkable similarity between lethargic encephalitis and botulism. The presence of certain symptoms, such as erythema and dryness of the mouth, makes for botulism. The patient during the outbreak of the eruption had suffered from dryness of the lips and tongue. His occupation as waiter in a restaurant may have exposed him to the *Bacillus botulinus*. Nevertheless encephalitis lethargica has also presented rashes. The diagnosis seems to have been left unsettled.

News of the Week.

Boys and Girls Drug Users.—In a report made by Albert Weber of New York, chairman of the Committee on Narcotic Drugs and Crime of the American Institute of Criminal Law and Criminology, at its annual meeting held in Indianapolis last week, the statement was made that 75 per cent. of the narcotic drug addicts in the United States are boys and girls approximating 16 years of age.

Proposed Radium Institute.—Effort is being made to secure a vote of credit of 2,500,000 francs from the Paris municipal council for the purpose of establishing a radium institute in Paris, to be directed by Mme. Curie, joint discoverer with her late husband of radium. This move is said to be the outcome of the recent announcement by Mme. Curie of important changes in the method of the therapeutic use of radium.

Wall Street Generous to Downtown Hospital.—After the recent explosion in the New York financial district Wall Street gave substantial expression of appreciation of the prompt and efficient aid rendered by the Broad Street Hospital to the victims of the disaster. Subscriptions were taken up on the Stock Exchange, the Cotton Exchange, the Consolidated Exchange, the Produce Exchange, and on the Broad Street curb. The sudden emergency is said to have practically cleaned out the hospital and the donations were urgently needed for replenishing the stock of medicines, drugs, and other supplies.

Volunteer Hospital Needs Funds.—A plea has been issued by General Ballington Booth, president of the Volunteer Hospital, located in the financial district of New York City, for $5,000 which is very much needed for the general work of the institution.

Central Housing Commission Suggested.—Dr. Royal S. Copeland, Health Commissioner of New York City, has announced his intention of going before the special session of the Legislature this month with recommendations dealing with the housing question. He will propose the appointing of a Central Housing Commission "with power to handle all rent problems, to determine what is essential construction, to pass on all plans for building operations, to determine zones for dwelling construction, to seize houses withheld from occupancy because of exorbitant rent demanded and rent them at reasonable prices to the homeless." The commission should have the authority to erect buildings for the laboring classes, and to determine the conditions under which they should be rented or sold, and to offer bonuses to private individuals who will erect homes. The Legislature, according to Commissioner Copeland, should grant the city power to issue bonds for building purposes.

Microscopist Wanted.—The United States Civil Service Commission announces an examination for

microscopist to fill a vacancy in the office of the Surgeon General, Army Medical Museum, Washington, D. C. Applications must be filed with the Civil Service Commission in Washington, or the Secretary of the local Civil Service Board, before Oct. 19.

Obituary Notes.—Dr. JOHN JOHNSON KYLE of Los Angeles, Cal., formerly of Indianapolis, Ind., died Aug. 29 from pneumonia, at the age of fifty-one. He was graduated from Miami Medical College, Cincinnati, in 1889, and specialized in otolaryngology. He was professor of rhinology, laryngology and otology in Indiana University, Medical Department, at Indianapolis, from 1900 to 1912. Upon his removal to California he became affiliated in the same capacity with the College of Physicians and Surgeons, University of Southern California. During the Spanish-American War Dr. Kyle served as Major with the One Hundred and Sixtieth Indiana Volunteer Infantry, and as acting brigade surgeon; during the World War he served as Major, M. R. C., U. S. Army, receiving his discharge in Jan., 1918. He was a fellow of the American College of Surgeons, member of the American Medican Association, Association of Military Surgeons, the American Laryngological, Rhinological and Otological Society, the American Academy of Ophthalmology and Oto-Laryngology, and various State and local medical bodies.

Dr. HENRY BULLWINKEL of Brooklyn, N. Y., died Sept. 14, at the age of fifty-five. He was graduated in medicine from the Bellevue Hospital Medical College with the class of 1888.

Dr. JAMES T. GIBSON of Yonkers, N. Y., died Sept. 16 at Ramapo Farm, Ramsey, N. J., at the age of sixty-four. He was graduated from Bellevue Hospital Medical College in 1886. He was a member of the Medical Societies of the County of Westchester and of the State of New York.

Dr. R. H. ANDREWS of Philadelphia, editor of the *Medical Summary*, died Sept. 17, at the age of seventy. He was graduated from the University of Pennsylvania School of Medicine in 1874, beginning the practice of medicine in Kulpsville, Montgomery County, Pa. In 1876 he moved to Lansdale, Pa., where he became proprietor of a daily newspaper, continuing, meanwhile, the practice of medicine. The *Medical Summary* was founded in 1879, and in 1900 Dr. Andrews retired from active practice to devote his time to his editorial duties.

Correspondence.

PARA-COCCYGEAL FISTULA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—You will admit that it was rather a strange coincidence that there was a little group of surgeons who were much interested in para-coccygeal fistula for a period of weeks, when suddenly a timely editorial upon that very subject appeared in the MEDICAL RECORD, which appearance served to add new concern to what had been rather a desultory exchange of ideas. It rendered methodical the unmethodical sort of inquiry that is generally known as "picking brains," which is but a term for a quest for information. Among the aforesaid group was Dr. Frink who had had quite a number of cases of the condition and he thought that sacro-coccygeal infundibuliform fistulas were not found among children, therefore I showed him three patients aged 18 months, 26 years, and 53 years. Some other medical men were rather surprised that I could go at once and produce from my clinic three well marked cases of a condition that they had never so much as seen. Whereas I was quite equally surprised to learn that the condition was considered rare. It is useless to regret now that careful records were not kept concerning the condition; but the truth is that most of the examples were revealed by an examination that had for its initiation the exploration of damage due to trolley or other accident; consequently any and all sorts of fistulæ became minor issues. All that can be said is, that it is now apparent that its lack of notice or mention is quite equaled by the lack of success that follows its usual, though very unsatisfactory treatment. And this is stated because the cases that drift into the writer's hands have generally been operated upon again and again while, so far as any curative results or improvement have been observed, a fair conclusion would be that those cases might better have been let alone. Some of them had fistula openings on both sides of the lumbar spinous processes with scars from the operation at or near the sacro-coccygeal junction. Additional scars and longer canals were the apparent changes and could hardly be rated as improvements. The roofing over by a heavy cicatrix confined the pus, but allowed and ensured subdermal burrowing. For the purposes of this letter Dr. Frink has been written to so that the following words have been quoted from his reply. "Speaking of coccygeal fistula, resulting from the breaking down of a pyo-nidal cyst or a cyst located on the ventral surface of the coccyx to which it lies close and near the distal end of which it is attached; such a cyst often contains hair. While I have had a number of cases among adults I never saw the condition in an infant until I saw your case last week (July 27), the cases I have had have been operated upon before they ever came into my hands, some were operated upon four times and still all the bad conditions returned because not one of the patients had had any portion of his coccyx removed. With my experience I do not believe that the condition can be cured without bone removal, to the minimum extent of the terminal coccygeal segment. Such a removal enables one to attack the cyst wall and to remove that. I have cut out the entire fistulous track, the whole coccyx together with the tissue that lay upon the ventral side of the bone with the cyst included in the mass, which whole mass I have then submitted to the laboratory for examination and section whereby it was demonstrated that the proximal terminal of the entire tract was to be found in the cyst that was located as stated above. In the actual operation the position of the patient using a general anesthetic is of importance and should be a true chest or a reversed Trendelenburg with the patient's face downward (prone) while the table should be raised. A vertical incision should be made over the coccyx with an elipse surrounding the fistulous opening;

the incision should be deep and it should be prolonged to the tip of the bone itself. When properly made the incision frees the entire tract but leaves it embedded in fatty tissue so that one may view a pedicle extending deeper and to the ventral surface of the bone. At this point your chisel-knife is of great use in cutting away the ligaments at the side of the coccyx and also in penetrating between the segments that have been selected for removal, in addition to the distal segment. After penetration the chisel-knife is used to pry up the bone in such a way as to put the ventral attachments on the stretch, thus making it easy to clamp and divide them. The bone is freed and together with the mass is removed, the clamped ligamentous attachments are held in such a way as to be included in the deep stitches that are now inserted and a proper support of the lower end of the rectum and of its sphincters is made sure and the depth of the opening that is to be healed is at once reduced. These sutures are of No. 3 twenty-day chromic catgut, are interrupted and are three in number; above which the wound is generally closed with deep silkworm gut stitches, and a small twisted drain of catgut is inserted. The dressing is of purple with a gauze pad well strapped down upon it. The after-treatment is merely a repetition of purple and tight dressings, but the patient gets out of bed in a day or two."

I think that every patient at the Knickerbocker Hospital was out of bed the day after operation. If there was any exception it would surely have made an impression. In studying the whole matter the writer has been impressed with the fact that the infundibulum or canal was congenital and a relation to the dermoid family because, as the doctor states, hair is often in the pyo-nidal cyst; but it is found elsewhere in the tract also, while the mouth of the canal is frequently stopped by a tuft of living projecting hairs or by a structure that is similar to a hair-mole with its hairs following the usual darkening and hypertrophy that come with advancing years. When the track of the canal may be felt below such a plug containing hair, the case calls for further investigation even though a probe may rarely be passed unless the canal is much dilated through being converted into a pus carrier.

Many infundibula are to be discovered through search that are not and apparently never have been inflamed so that it would seem quite possible that an infection has a rectal source. Some patients demonstrate a rectal fistula that has broken into the pyo-nidal cyst or into its canal, for they yet possess the connection *in toto*, but others show that there has once been a hole in the rectal wall with the cicatrix of a tract that once existed therefrom. Both hole and tract are now healed; but the infected cyst or canal has become pyogenic on its own account, as an independent incubator. Call the condition a blind external fistula if you wish; but also call to mind that when the pus does get into the cyst or the infundibulum it is bothering some hospitals a good deal, for the final clean-up appears to be coming into the present writer's hands. The whole appearance of the condition may be so misleading that the junior assistant incises a furuncle in the midcoccygeal region, after which small error various members of the visiting staff convince themselves that they cannot or do not seem to be able to correct that error or to do anything else that is really worth the doing. If the writer has helped one such it is a sufficient excuse for his letter.

DOUGLAS H. STEWART, M.D.

128 WEST EIGHTY-SIXTH STREET,

CESAREAN SECTION VS. CRANIOTOMY.

TO THE EDITOR OF THE MEDICAL RECOTD:

SIR:—In the article by Dr. R. A. Bartholomew, on "The Prevention of Peritonitis in a Case of Intrapartum Infection Subjected to Extraperitoneal Cesarean Section," in the MEDICAL RECORD of June 26, the author proves that the method of operating was successful in preventing peritonitis. I beg to be excused for expressing the belief that several readers would like to know the internal measurements of the pelvis in the case described; and if the conjugata vera was above 5.5 cm., I would suggest that craniotomy by means of Tarnier's basiotribe, which reduces the *base* of the skull, would have been preferable. The basiotribe is the most efficient instrument for these cases. . . When difficulties arise in bringing an intact base through the superior strait of the pelvis, I use the sharp hook to put the base upon its side. These are the only cases in which the old-fashioned sharp hook is still an excellent aid to the accoucheur.

VALPARAISO, CHILE.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 27, 1920.

What Governs Heredity.—Views as to heredity do not agree and the question will be earnestly discussed at the meeting of the British Association, which is now being held at Cardiff in Wales. The botanical, the zoological, and the geological sections will be vigorously employed in discussing the problem of heredity and the factors that influence it. Miss Saunders presides over the botanical section and will deal with the subject from the point of view of a convinced Mendelian, querying only the ideas of Morgan the American Mendelian with regard to the mechanism of inheritance. Miss Saunders concludes that so far as experimental evidence goes, all the variations which a child or a chicken or a sweet pea exhibit are shut up in the egg or the germinal egg cells from which they spring, and that outer circumstances or environment cannot alter these in the slightest degree, simply because they are immutable. But by no means all those who attend the meeting are hard and fast Mendelians. Their contentions will be hotly disputed, among others by Dr. F. A. Bather, the president of the geological section, by Professor Dendy and Dr. Ruggles Gates. Mr. Stanley Gardiner, president of the Zoological Section, is expected to side with the followers of Mendel, of whom in Great Britain Professor William Bates is the high priest. The Mendelian theory

is that nothing can change what the germ cell can or will do except another germ cell that fuses with it. Supporters of this idea stand in a strong position because they have been able to experiment in this direction and in spite of many failures have had some successes, notably have produced certain valuable kinds of wheat by carrying their theories into execution. Their opponents stoutly assert that the Mendelians claim too much and that their successes do not justify such extravagant claims. Why take for granted on these grounds that neither environment in nature, nor the other cells of the animal or plant which are in proximity to the germ cells are impotent to affect them? The meeting of the British association over and above the deeply fascinating question of inheritance will discuss many matters pertaining to medical science. For example, the new section of psychology bristles with papers on the psychology of industrial life. I shall in succeeding letters consider in some detail certain subjects debated at the meeting which may be of concern to medical readers.

Rats and the Reported Plague in Paris.—Plague has been reported in Paris and although the report lacks official confirmation credence is given to it in many quarters. The *Sunday Observer* of August 22 makes reference to the matter in its Paris correspondence and states that rats are being blamed for the reported appearance of plague in the French metropolis and goes on to say that it is time something were done with the Paris rat. If you are abroad after nightfall dozens of rats will be seen emerging from the gratings around the trees. The sewers swarm with rats. Eugene Sue, in his gruesome and realistic description of the "Mysteries of Paris," devotes a considerable space to a vivid word picture of the condition of the Paris sewers and of the hordes or rather armies of rats. According to his account the rats which infest or dominate underground Paris are well disciplined and under able leadership. The Paris correspondent of the London Sunday newspaper in a further part of his letter says that with regard to the plague, while there seems no reason to doubt that what is euphemistically called *"mal de Yersin"* is really the pest there is not any occasion for alarm. He ends the paragraph on the subject with the statement that there is not the slightest fear of an epidemic, provided there is no negligence. There appears, then, to be little doubt but that plague exists in Paris. It is true that with the enforcement of up-to-date scientific measures the disease cannot spread, but the fact that plague has found its way to the very center of civilization affords a striking object lesson on the necessity for the wholesale destruction of rats. Without the aid of the rat plague cannot be propagated and for this reason alone the most untiring and energetic efforts should be made to get rid of the pestilential rodent. Last year a country-wide campaign in Great Britain against the rat was inaugurated and advertised, but from want of support and especially of proper organization, little appears to have been done. It is difficult to convince the ordinary citizen that the rat is a serious public menace and in particular that he is a grave menace to health. Moreover, the problem is an international one. The rat conveys plague from the Far East because he is carried on ships which go to and fro. The campaign against the cunning beast must therefore be well organized and international if it is to be successful.

Alcohol and Its Influence on Body and Mind.—Sir Frederick W. Mott, a British neurologist of the widest experience, gave a lecture on body and mind at the thirty-first congress of the Royal Sanitary Institute held at Birmingham on July 19 to 24, 1920. In the course of this lecture he discussed alcohol and its influence on body and mind. He pointed out that, like syphilis, it is a race poison and that owing to its widespread abuse it is the most important cause of disorders of conduct and crimes of violence, as prison statistics show. But Mott also drew attention to this very important fact and one which practically unknown to the layman and frequently misunderstood by the medical man that alcohol is not so potent a cause of insanity as asylum statistics would seem to indicate. Why then, he asks, is it assumed to be such a cause of increase of insanity? Firstly, because the data upon which the statistics are made are unreliable. Secondly, because potential lunatics, epileptics, and the feeble-minded have only a narrow margin of highest control, and a relatively small quantity is sufficient to make them anti-social, and thus reveal the unsound mind, so that they become certifiable. Mott gave statistics in support of these conclusions. There is thus no doubt that persons who have suffered with head injury or brain disease are intolerant of alcohol. The speaker emphasized the self-evident truth that alcohol and syphilis work together in undermining the constitution and that alcohol plays an important part in the spread of venereal disease. Mott holds the view that control of the liquor traffic, especially of the sale of spirits, is necessary in the public interest, but he does not favor absolute prohibition. The sale of alcoholic beverages in the form of light beers and wines seems to be a reasonable mode of dealing with the question, and not likely to cause the widespread discontent that total prohibition would.

Hospitals on the Rates.—Clause 2 of the Ministry of Health Bill, presented by Dr. Addison, the Minister of Health in the House of Commons, on August 16, contains the following: (1) The council of a county shall have the power (a) to supply and maintain hospitals for the treatment of illnesses and diseases generally, or for the treatment of any particular illness or disease, or any particular class of illnesses or diseases, and (b) to contribute, on such terms and conditions as may be approved by the Minister, to any voluntary hospitals or similar institutions within their area, and (c) to undertake the maintenance of any poor-law hospitals or infirmaries within their area, and (d) to establish and maintain or to contribute toward the cost of or otherwise aid in establishing or maintaining an ambulance service for dealing with cases of accident or illness within their area. (2) The councils of two or more counties may, with the consent of the Minister and subject to such conditions as he may prescribe,

combine for the purpose of supplying and maintaining hospitals under this section, and where any councils so combine they may appoint a joint committee under section 81 of the Local Government Act, 1885, and that section shall have effect accordingly. Divested of legal phraseology this bill conveys obliquely the policy of the Ministry of Health with respect to the voluntary hospitals, namely, that local authorities may contribute to the maintenance of voluntary hospitals and other voluntary institutions. Thus, it seems likely in the near future that hospitals will be rate-aided to this extent; that the public health authorities will pay for those patients who, were there no such institutions available, would become a charge upon the rates during illness. It appears also probable that ere much time has elapsed the pay-ward system will be introduced into the British hospitals generally. This, it is to be presumed, is the purpose of the bill.

Malaria in England.—Mosquitos are prevalent in parts of England and taking into consideration the fact that there are thousands of ex-service men in the country who are laden with malaria, the matter cannot be dismissed lightly. In the *Morning Post* of August 18 last there appeared a striking and well reasoned leading article in which while it was pointed out that indigenous cases of malaria are rare in London, as indeed they are everywhere in Great Britain, except, perhaps, in the southeastern counties, emphasis was rightly laid upon the part played by the mosquito in spreading the disease. But after all it is not the rare or comparatively rare indigenous cases of the infection by which the disease is spread. A very important factor in the propagation of malaria is the presence of cases of the malady from which the anopheline mosquito may acquire the virus, which it not only transmits, but which undergoes a definite cycle of development in its body. According to authorities here there are three species of anopheles in Great Britain which are known to be malaria carriers. These principally congregate in the vicinity of the big city centers as London, Liverpool, Manchester, and Glasgow, where are also many ex-soldiers who have come infected with malaria from mosquito infested countries and districts, such as Palestine, Salonika, India, and the east and west coasts of Africa. There does exist, therefore, a certain amount of danger of outbreaks of malaria among the community at large. On the southeast coast there are breeding places and anopheles have been found. It is a question then whether treatment of breeding places and other precautions should not be taken against the spread of malaria, on the principle that prevention is better than cure.

Obituary.—A great English surgeon has passed away recently at Sheffield in the person of Lieut.-Colonel Sinclair White, late Professor of Surgery University of Sheffield, at the age of 61. He had just retired from active practice. His career was proof, if such proof is needed, of what a man can achieve by his own unaided efforts provided he possesses brains and will power. He came to Sheffield forty years ago after finishing a brilliant student's course at Queen's College, Galway. He commenced in Sheffield in a modest way and for many years his work was of a very uphill nature. However, after struggling and succeeding, he received his first surgical appointment in connection with the Sheffield Hospital for Sick Children, which was followed by his appointment to the Royal Hospital, Sheffield, and finally he was asked to join the staff of the Royal Infirmary as surgeon. From then on he made rapid strides as an operating surgeon, and was regarded as a master of his craft, resourceful and able to meet any eventuality. He did magnificent work during the war, and his name in this direction is well known to American surgeons. The strain of the war work undoubtedly hastened the breakdown, which ended fatally. Sinclair White was a man who was not so well known as he deserved to be. He did not write, because his surgical experience came so late in life that he was too busy to do so. But he will be remembered by all who knew him as a really great surgeon.

OUR LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, Sept. 1, 1920.

Control of Venereal Disease in Denmark.—Since the control of venereal disease is now occupying the minds of the medical profession in all countries, it may be of interest to refer to the laws applied in Denmark, as they have unquestionably borne fruit. Paragraph 181 of the criminal law reads: "Whoever, knowing or suspecting that he has a venereal disease, has sexual relations with a person (free from such infection) may be sentenced to imprisonment, or when there are aggravating circumstances, to labor in a house of correction." There is no control over prostitution by the police, as in many other European countries, but a prison sentence or prison with hard labor can be given by the courts to those who keep brothels, incite minors or others to debauch, or who rent rooms for immoral purposes. Paragraph 181 is applicable to anyone who, in the above-mentioned circumstances, infects his or her conjugal partner if a claim to that effect be made within one year. If a person infects another person who is unaware that there was danger of infection, the former shall be compelled not only to pay the expenses of treatment of the person he has infected, but also damages for loss of time or suffering that the disease may have caused.

Any person with a venereal disease, whether he has or not means for paying for treatment, can be treated at the expense of the public revenues, and he must submit to such treatment unless he can prove that he is being properly cared for by his own physician. If the case is such that transmission of the disease to others can be prevented only by isolation of the infected person, or if the latter does not observe prescriptions destined to prevent contagion, he can be interned in a hospital for treatment. All beneficiaries of public charity who are found to have a venereal disease will be detained in a hospital for treatment. When, during or at the end of treatment, it may be necessary—on account of the danger of transmission—to keep the subject under observation, the physician should order the patient to return at regular intervals or furnish

a written proof that he has followed treatment with another physician. The city physician furnishes the patient with the necessary printed forms for this purpose. If the patient does not furnish this proof, the competent public medical authorities are to be notified and the patient compelled to present himself at the consultation bureau, otherwise he is liable to arrest.

Any physician who examines or treats a person for a venereal disease must call the patient's attention to the contagious nature of the affection and the legal consequences resulting from transmission of his disease to another. The physician must also especially see that the person does not marry so long as danger of transmission of the disease exists. In their weekly reports to the city physician or district physician, physicians must expressly certify that they have conformed to the above rules and indicate the number of persons to whom they have given the necessary instructions. Otherwise the physician is liable to a fine of 200 crowns (about $56). Anyone who gives a false name, profession, or address to a doctor is liable to criminal proceedings.

A syphilitic infant can be nursed only by its mother. On the other hand, a wet nurse knowing or suspecting that she has syphilis cannot nurse the child of another. A child is considered suspect of syphilis—even when it has not presented symptoms—when its parents have contracted syphilis less than seven years before or when the birth dates more than three months after they have contracted the disease.

Foreign Physicians Flocking to Switzerland.—On account of the precarious economic conditions of many European countries the number of foreign physicians desiring to come to practise in Switzerland, especially in health resorts, is greatly increasing. Thirty-eight came up for examination before the Federal board for examination in 1919. The situation is somewhat complicated by the fact that certain countries, particularly Germany, refuse the right to practise in their territory, even when the physician has received his M.D. from one of their universities. He may, however, receive the right to practise if he becomes a naturalized German citizen. This question has been recently examined by the Swiss Service of Public Hygiene and the discussion ended with the conclusion that the best means was to make the Federal examinations and also the conditions for admission to the preliminary examinations more severe. Among these it was suggested that all foreign candidates for admission to the Swiss medical schools should be required to have resided a certain number of years in Switzerland, during which they had prepared for and passed their preliminary examinations for the universities. In 1919 there were 1,021 examinations of candidates in medical schools, while in 1918 there were 907, 858 in 1917, and 705 in 1914. The increase was almost exclusively in medical examinations, which were 298 in 1918 and 389 in 1919, while the number of examinations for dentists, pharmacists, and veterinary surgeons remained about the same as in 1918. The number of examinations in the natural sciences was 358 in 1919 and 353 in 1918. It may be concluded from these figures that the present afflux of candidates for examinations in medicine is simply the consequence of the general upheaval in university studies throughout Central European countries.

The 1,021 examinations—170 of which were unsuccessful—were as follows: 900 examinations for the first time with 133 unsuccessful results=14.8 per cent.; 100 examinations for the second time with 35 failures=35 per cent.; and 21 examinations for the third time, with 2 failures=9.5 per cent. Of the 1,021 candidates 969 were Swiss, the remaining 52 being foreigners, Germany heading the list with 18, Poles 8, Russians 5, French 4, Galicians 3, Roumanians, Austrians, and Greeks each 2, while there was 1 each from England, Spain, Serbia, Portugal, Italy, Belgium, Luxembourg, and Holland. For a small country like Switzerland, with a population of some five millions, the above figures are interesting.

Progress of Medical Science.

5. Endometritis: Its Pathology and Differentiation from Malignancy. W. Claude Usher.

2. Gastric and Duodenal Ulcers.—McClure and Reynolds present material from the medical clinic and the radiographic department of the Peter Bent Brigham Hospital, Boston. In order to appreciate better and to evaluate more properly the significance of the different diagnostic methods as aids in diagnosis and to comprehend better their relative importance, they made an analysis of the records of eighty selected cases of duodenal and gastric ulcer. Fifty-five diagnoses were confirmed by operation. In the remaining cases the *x*-ray findings or frank hematemesis made the accuracy of the diagnosis practically certain. Forty-six of the cases occurred in men and thirty-four in women. From this analysis they formulate the following conclusions: The symptomatology of peptic ulcer may be divided into typical and atypical groups. The typical type, by the aid of radiographic findings, may be diagnosed with a high degree of accuracy. In the diagnosis of the atypical class *x*-ray studies are of the utmost value; in many cases the diagnosis cannot be made without the aid of radiographic findings. *X*-ray studies should form a part of the physical examination of every gastrointestinal case. Their importance in the diagnosis of peptic ulcer is second only to that of the history of the case. *X*-ray studies are the most efficient and accurate aids in the differentiation between functional and organic pyloric obstruction, and between ulcer and cancer. In the great majority of cases laboratory findings are of less value as an aid in the diagnosis of peptic ulcer than those obtained from radiographic studies. The laboratory findings valuable in diagnosis are gross amount of blood in the vomitus or gastric contents, the frequent vomiting of old food residues, and tarry stools. Findings of less value are the persistent presence of occult blood in the stools, the presence of food residue in the gastric contents, and the presence of free hydrochloric acid in the gastric contents.

4. The Relationship of the Anemias to Life Insurance.—H. Z. Giffin holds that the increase in the incidence of pernicious anemia makes it advisable to consider this disease separately in mortality statistics, rather than to include it among anemias in general. Medical examiners should be required to report the hemoglobin estimation of each applicant. Blood smears forwarded to the laboratory of the central offices by examining physicians would be of great assistance in eliminating for insurance applicants with pernicious anemia and leucemia. The refusal of all applicants with anemia without a definite understanding concerning the possibility of later reapplication and acceptance may be a serious injustice to the individual. Applicants with anemia from chronic recurrent hemorrhage, anemia from insufficiencies of diet, or as a result of functional dysphagia, may be expected to recover within one year at most after proper treatment, and should be given the privilege of reapplication at a subsequent time. Applicants who have had splenectomy for splenic anemia, provided cirrhosis of the liver, gall-bladder disease, and thrombosis of splenic vessels are not present, might be considered acceptable risks for term insurance after having been well for five years following operation. Applicants who have recovered following splenectomy for hemolytic jaundice may safely be considered for a more liberal form of policy if they have remained well for five years.

2. Acute Infectious Myoclonus Multiplex and Epidemic Myoclonus Multiplex (Epidemic Encephalitis).—J. Ramsay Hunt calls attention to the fact that the condition under discussion may appear in sporadic and in epidemic form. The isolated or sporadic form is quite rare. He reports two cases coming within this category. Epidemic myoclonus multiplex, on the other hand, has been of frequent occurrence during the last winter, and represents a special type of epidemic encephalitis. He reports seven cases of the epidemic form. From the study of these cases he draws the following conclusions: The acute infectious myoclonus multiplex may be regarded as a definite clinical type of acute neural infection. In its epidemic form, it is a part of the large clinical group that has been so prevalent during the last two years in this country and in Europe—the epidemic of lethargic encephalitis. The relation of the sporadic to the epidemic type of infectious myoclonus multiplex is still problematic, although it would appear probable that they are of similar origin, and that the epidemic encephalitis has been appearing for a considerable time unrecognized, in certain sporadic forms. That the disorder is of infectious origin and referable to a microorganism or its toxic product is made clear by the mode of onset, course and general symptomatology. As to special etiologic considerations, it would appear likely that a special strain of the organism has acquired an affinity for certain tissues of the nervous system, and in this way the peculiar and very limited clinical reaction of infectious myoclonus multiplex has been produced. Other factors of a more theoretical nature may also be considered, as exhaustion or biologic inferiority of certain neural systems which render them more susceptible to the deleterious influences of disease. To those who are interested in the theory of the elective localization of bacteria, the organisms or virus obtained from cases of this clinical type, with its peculiarly limited form of neural involvement, would offer especial advantages for experimental study.

3. Acute Methyl Alcohol Poisoning.—Raphael Isaacs tabulates a series of cases treated by alkalization and another series not receiving alkalization. He holds that there is a rapid disappearance of the symptoms, unless the anatomic injury is beyond repair, with intensive alkali therapy. Many of the toxic symptoms probably accompany the acidosis, which may be associated with the acid production (formic) and with methemoglobinemia.

5. The Blood and Urine in Pancreatic Disease.—Cammidge and his associates summarize their clinical observations as follows: 1. The urine in disease of the pancreas contains an excess of dextrin, which can be measured by the iodine coefficient, and less accurately by the difference value of the urine. 2. The difference value of the blood in pancreatic disease varies directly with the iodine coefficient of the urine and is probably due to the same cause—namely, an abnormal dextrin content. 3. The difference value of the blood, and the iodine coefficient of the urine, are highest in the fasting state and gradually diminish after a meal for about three or four hours, returning to the fasting level after another three or four hours. 4. The difference value of the blood and the iodine coefficient of the urine vary inversely as the percentage of sugar in the blood after a meal. 5. The difference value of normal blood ranges from 0.002 per cent. to 0.008 per cent., and is not appreciably influenced by the ingestion of food. 6. The amylolytic ferment of the blood, and of the urine, is increased in disease of the pancreas proportional to the fasting difference of the blood and the iodine coefficient of the urine. 7. The amylolytic ferment of the blood and urine in pancreatic disease varies directly with the percentage of sugar in the blood after a meal, and inversely as the difference value of the blood and the iodine coefficient of the urine. Animal experiments confirm the conclusions arrived at on clinical grounds, and in addition show the following: (1) The rise in the difference value of the blood resulting from interference with the functions of the pancreas insufficient to produce frank hyperglycemia and glycosuria, diminishes as the volume of the gland is further reduced and the percentage of sugar in the blood and the excretion of sugar in the urine rise. (2) The hydrolyzable substance in the blood on which the difference value depends appears to be derived chiefly from the glycogen stores of the liver, and is an intermediate soluble product (dextrin) formed in the conversion of glycogen to sugar. (3) The liver contains an amylolytic ferment which passes into the blood and urine, and it is as a result of its activity that the glycogen of the liver is broken down. (4) The pancreas exerts a restraining influence on the glycolytic ferment of the liver, probably through its internal secretion. (5) Normally, the balance between the glycolytic ferment of the liver and the internal secretion of the pancreas is maintained in such a way as to keep the percentage of sugar, and the difference value of the blood, within well-defined limits; when this balance is interfered with abnormal relations result. (6) A relative increase in the pancreatic secretion causes a fall in the percentage of sugar and in the difference value of the blood. (7) A relative diminution in the secretion of the pancreas, with consequent greater liberty of action on the part of the glycolytic ferment of the liver, gives rise in the early stages to

an increased formation of the intermediate products of glycogen degradation without any change in the sugar, and in the later stages to an increasing sugar production with a proportional diminution in the intermediate products. (8) The appearance in the blood and urine of intermediate products of carbohydrate metabolism, as shown by the difference value of the blood and the iodine coefficient of the urine, indicates a prediabetic condition which, if allowed to progress unchecked, will be followed by hyperglycemia and glycosuria. (9) Incidentally it has been shown that a considerable proportion of a well-boiled starch is absorbed into the portal circulation in the form of dextrins and maltose, whereas an uncooked starch enters the portal blood chiefly as dextrose.

1. Puerperal Sepsis.—Victor Bonney, in this introductory paper of the discussion on puerperal sepsis, read before the Section of Obstetrics and Gynecology of the British Medical Association, said the solution of the problems of prevention and cure of septic infection of the puerperal uterus necessitates the correct answering of the following questions: 1. What is the original source of the organisms? 2. How do they get into the uterus? 3. What is their exact situation by the time they have produced symptoms of sepsis? Answering the first, he states that in nearly all severe cases of puerperal sepsis the streptococcus, either alone or in conjunction with *B. coli communis* is the predominant organism. The infection may be autogenous or heterogenous. The most obvious manner in which the organisms could obtain entrance into the uterus is that they should be carried directly there on hands and instruments. That this sometimes happens there can be no doubt, and it is especially dangerous when the introduction takes place after the expulsion of the placenta and membranes has left the uterine wall bare to direct infection. But in far the larger number of cases of puerperal sepsis no introduction of anything into the uterus has taken place, the most that could have happened being the implantation of organisms into the cervix or vagina. It is certain that organisms transplanted into or originally present in the vagina must in some way be transported into the uterus subsequent to the labor. Bonney refers here to the experiments of Bond, who showed that minute particles of indigo, carmine, or litmus placed in the cervix and upper vagina could be detected in the Fallopian tubes in about twenty hours, having been carried up, apparently, by an ascending current in the secretion from the wall of the uterus. Bond's work, he holds, offers a complete explanation of the facts that the symptoms in a large proportion of the cases of puerperal sepsis appear much later than they should do if the disease were due to direct implantation of organisms on the uterine wall during labor. Another possible route of infection is the transmission of organisms direct from the bowel to the uterus across the peritoneal cavity or to the vagina through the rectovaginal septum. The situation of the organisms by the time the symptoms of sepsis are produced is of the utmost importance in regard to curative treatment. He reiterates that as a rule puerperal sepsis is *not* associated with the retention of gross fragments of placental tissue in the uterus. He emphasizes the point that uterine sepsis, taking all cases into consideration, both those after labor and those after miscarriage, occurs quite as commonly with a completely as with an incompletely emptied organ. Were the organisms causing the symptoms commonly located in tissues easily removable from the uterus the problem of the curative treatment of the condition would be a simple one, but unfortunately this is not so. The organisms are situated *in* the uterine wall, almost from the beginning of the infection, and very shortly afterward attain, *via* the veins or lymphatics, to positions deep in, or beyond it. Of the various routes of infection, that along the veins draining the placental site is the commonest and most important, and since, as a rule, the placenta is situated in the upper segment, it is along the ovarian veins that the infection most commonly spreads. Puerperal sepsis is a variety of wound infection in the treatment of which both operative measures and the direct application of antiseptics have a very limited scope, and efforts to find some other way of efficiently attacking the organisms have been only partially if at all successful. Prevention is more to be relied on than cure. The finding of the substance, whatever its nature, that is the real antidote for puerperal sepsis is probably reserved for some laboratory worker of the future, but in the prevention of the disease every practitioner of obstetrics can take a hand.

6. Improvement in Graves' Disease Subsequent to Severe Focal Infection.—Theodore L. Squier presents the histories of two cases of hyperthyroidism in which complicating infections first caused marked increase in the severity of the thyroid symptoms later followed, after the acute infection had subsided, by striking improvement if not cure. He considers it not improbable that the improvement seen was due to actual loss of secretory tissue through postinfectious sclerosis of the gland.

8. Some Observations on Chronic Arthritis.—George Draper suggests that chronic arthritis represents a very profound constitutional disturbance in which forces analogous to those concerned in acromegaly and thyroid insufficiency are concerned. The family and personal history which arthritic patients give of hives, angioneurotic edema (bee sting effects) and asthma, and, in addition, the well-known feature of joint involvement seen in serum disease, all seem to indicate that there is a relationship between this whole group of phenomena and chronic arthritis.

Blood Transfusion.—Odelberg in sketching the history of transfusion mentions one episode in which Harvey's discovery was long antedated, but nevertheless the latter is the step which must logically have preceded such a practice. Transfusion began properly with Blundell, an English obstetrician, who used human blood and obtained some successes. Defibrinated blood was next introduced and held the stage for many years. In 1859 Martin collected a list of obstetrical cases num-

bering 57, in 43 of which a good result had been obtained. In 1879 Eck first successfully sutured blood-vessels. The introduction of saline infusion retarded advances in blood transfusion until about 1900, when Crile and others revived the latter in its modern form. The author reproduces the technique of Jeanbrau and of Lewisohn and from the writings of Hunt, Jeanbrau, Sanford and others compiles six groups of indications as follows: primary anemia, secondary anemia, hemorrhage, acute toxic and septic conditions, leukemia and shock. Of the twenty-one references in the bibliography fourteen are from America and no less than four of the papers quoted appeared in the *Texas State Journal* during 1917-8, the contributors being Goar, Graves, Hunt and Starley. Other Americans quoted as Archibald, Pemberton, Sanford, Snyder, C. G. Watson, Robertson, Wilson, J. J. Watson, Rous and Primrose. These names are, of course, only a fraction of the total number of Americans prominent in transfusion since 1900, but they at least serve to show to what an extent the subject of transfusion belongs to the Western Hemisphere.

Small Doses of Ipecac in the Digestive Disorders of Bottle-Fed Babies. — Rousseau-Saint-Philippe brought this subject before the attention of the profession in 1913, but so far as he knows this drug has never been tested save in comparatively massive dosage. In testing the minute dose he was not influenced by the claims or theories of homeopathy, but by the small dosage visualized in serotherapy and in the use of metallic ferments. He sought both to obtain the action of the minute dose *per se* and of the minimum total dose by administration of small and repeated amounts of ipecac, choosing the latter in preference to emetine. The conclusions appended by the author to his elaborate article are as follows: artificial alimentation of infants is on the increase despite all efforts to increase breast feeding; bottle-fed babies are less vigorous and less resistant to disease than breast-fed, and from the very beginning they develop a form af dyspepsia which may be regarded as normal to the bottle-fed which may at any moment develop into a severe gastroenteritis; the conditions of physiological inferiority and bottle feeder's dyspepsia are the result of digestive insufficiency toward cow's milk, however closely this may be made to approximate breast milk, and lead to defective assimilation and nutrition, the exact cause of the shortcoming lying in the foreign protein nature of cow's milk; the quality of the digestion is shown by the differences in the stools as well as by the physical habit and the predisposition to disease. The drug ipecac is admirably calculated to antagonize this state of affairs by increasing the digestive secretions and by preventing putrefaction, one of its activities being to stimulate the biliary secretion. The author uses only the tincture, which he gives drop wise and increases with age. For the first three months one drop is given three times daily, and is then gradually increased, sometimes indeed to such a degree that a dose of seven or eight drops three times a day may occasionally be reached, although Saint-Philippe says that the child will usually thrive on a much smaller one.

Schweizerische medizinische Wochenschrift.

June 24, 1920, i, 26.

Therapy of Gonorrhea.—Bloch reminds the reader that forty years have elapsed since the discovery of the gonococcus, yet we have made far from satisfactory progress in the treatment of this affection. The literature of the subject of treatment is immense, but it is evident that the real reasons for failure of therapeutics in this field are not yet fully grasped. The author suggests that failure of the patient to cooperate with the physician is one main factor and that if the former played his part properly the number of cured cases would notably increase. The medical man is often to be blamed for injection-technique, which is put up to the patient, who in consequence may, instead of obtaining a good result, carry the infection more deeply into the organism. The expense of treatment is one of the worst drawbacks and the state should see to it that gonorrhea patients, if necessary, receive free treatment, while office hours should be such that the patients do not have to leave their occupation. The state should have the power to coerce those who do not seek to be cured. But the physician is often more to blame than the patient, because he does not keep abreast of progress or is not strict enough in handling his material. A distinction should be made between acute, uncomplicated cases and other types; there appears to be no reason why the former are not curable with a reasonable amount of pains and patience by the ordinary practitioner. These cases may be reached from without by injecting bactericidal remedies. The chronic or complicated case, on the contrary, may benefit by persistent systemic treatment of numerous sorts in addition to local treatment. The distinction between these "external" and "internal" types is not always marked, for the "external" cases often fail to yield to the injection treatment, and this may be due either to shortcomings of the injection technique used or to masked complications.

Le Progrès Médical.

June 26, 1920, xlviii, 26.

Etiology of Psoriasis.—Bory writes at great length on the various theories of the nature of psoriasis. He considers in succession the neurogenic factor, the nutritional or metabolic factor, the parasitic hypothesis, the deducibility of cause from successful therapeutics and finally the biologic and experimental aspects. Naturally all these viewpoints have backing. According to the test of local treatment the lesions might well be determined by parasites because they are mostly parasiticide ointments which are efficacious. Staphylococcus vaccines seem efficacious in certain cases, but it is easy to understand that no specific reaction is involved and other foreign proteins could doubtless exert the same power. The view that psoriasis is a tuberculide or, rather, paratuberculide opens up the possibility that from the very nature of psoriasis many factors might predispose to or determine the disease according to circumstances. From this viewpoint the tubercle bacillus or its toxins might be held responsible for certain cases of the disease. A symbiosis of Koch's bacillus and the staphylococcus has been accused. The author suppresses the curious fact emphasized by Sabouraud that in very many cases psoriasis is a disease of the "superhealthy," which may be said of very few affections, cancer being another. Cases are quoted of inoculated psoriasis, of conjugal cases, of familial and bunched cases, but all of these behaviors have been seen in cancer. The subject of psoriasis appears to be peculiarly sensitized to the action of some unknown principle and older authors used to cite the association of psoriasis with asthma in the same subject and same family. The author arrives at no conclusions and closes with a suggestion that the tuberculous theory should be tested further.

Disappearance of Ascites as a Consequence of Intraperitoneal Injections of Quabaine.—Cases of this sort have been reported in which it was taken for granted by the reader that the alkaloid had been injected intravenously—in the absence of any mention of the route used. This was known to have been true of a case reported by Dufour and Semelaigne in 1919, and this case led Damade of Bordeaux to test the intravenous route in a patient with cirrhotic ascites. Half a milligramme of the drug having proved inert, the patient was tapped and the injection repeated without positive result, the fluid at once collecting anew. Four intraperitoneal injections were now made in succession and without further tapping. The positive result was shown in increased diuresis with corresponding absorption of the fluid. The interval between injections was three or four days. Since the last injection the condition has remained at a standstill, diuresis being normal from day to day. Damade explains the result by a specific local action of the alkaloid on the peritoneum. —*Gazette hebdômadaire des sciences médicales de Bordeaux.*

Book Reviews.

DIÄTETIK DER MAGEN UND DARMKRANKHEITEN. Von Prof. Dr. T. BOAS, Nebst einen Abhunz; Diätetik vor und nach Operationen am Magen-Darmkanal, von Prof. Dr. G. KELLING. George Thieme. Leipzig: 1920.

THIS new book of Professor Boas is very timely. The dietary régime forming the most important part of the treatment of digestive ailments is its subject. Similar to some American clinicians Boas lays stress on sufficient nutrition and generally makes use of the common ordinary foods, which, however, in some instances require special preparation. The artificial foods and predigested nutritive materials play a very subordinate rôle. In the treatment of chronic obstinate constipation a lacto-vegetarian diet with exclusion of animal foods (meat or fish) is recommended. As soon as there is improvement noticeable a small amount of white meat (fish or chicken) is added once or twice weekly at first, later on oftener.

The book is written in the form of lectures and will be of great aid to the medical profession in assisting the dietary management of the dyspeptics.

The supplement by Kelling, dealing with the dietary requirements after operation on the gastroenteric tract contains a number of useful suggestions whereby the patient may be made more comfortable and his recovery may be accelerated.

L'ANESTHESIE LOCALE ET RÉGIONALE EN OTO-RHINO-LARYNGOLOGIE. Par les docteurs GEORGES CANUYT et J. ROZIER. Préface du Professeur E. J. MOURE. Paris: Gaston Doin, 1920.

THIS volume of nearly 200 pages and 117 illustrations comprises nine chapters devoted to generalities of anesthesia, the nose and nasal fossæ, larynx, ear, and appendages, palate—hard and soft-tonsils, tongue, thyroid gland, lips, and lower jaw. Hence it should be of equal value to the operating laryngo-rhinologist, the general surgeon, and the modern oral surgeon or operating stomatologist. But for the operating otologist with his mastoid and cranial cases it does not make the same appeal, this branch of activity coming under cranial surgery. One is reminded that there should be comparison volumes to cover other aspects of craniofacial surgery, with especial reference to surgical affections originating in the eye and ear. The book is an admirable effort, however, and is doubtless in part inspired by Professor Moure, the dean of laryngologists and almost the sole survivor among the original pioneers.

HUMAN PARASITOLOGY, with notes on Bacteriology, Mycology, Laboratory Diagnosis, Hematology and Serology, by DAMASO RIVAS, B.S.Biol., M.S., M.D., Ph.D., Assistant Professor of Parasitology and Assistant Director of the Course in Tropical Medicine, and of the Laboratory of Comparative Pathology and Tropical Medicine in the University of Pennsylvania; Pathologist to the Department of Health of Pennsylvania; Serologist to Friends Hospital, Frankford; Assistant Pathologist to the Philadelphia General Hospital, Ex-Research Fellow in Biology and Ex-Scott Fellow in Hygiene, University of Pennsylvania; Formerly Assistant to the Koch Institute, Berlin, and Coworker in the Pasteur Institute, Lille; Member of the Malaria and Tropical Diseases Commission for the Sanitation of Brioni, Istrie, and East Shores of the Adriatic, 1900-1902. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920.

IT is always a pleasure to welcome a new book when it is worth while, and this new book by Rivas is decidedly worth while. It is the first work on this subject which has appeared in English for a considerable time during which much progress has been made in the study of many of the protozoan parasites especially. Except for a brief mention of some of the cultural methods and characteristics, a study of bacteria is not included, the work dealing entirely with animal parasites—protozoa and metazoa. The author deals mainly with the anatomy and mode of reproduction, the symptomatology and treatment receiving comparatively scant attention, although being by no means ignored. His descriptions are very clear and are rendered more so by the excellent illustrations. The subject has grown to such size in the last decade or two that the author has had to be very concise, in some cases more so than the reader finds satisfactory; this is because, as Dr. Rivas intimates in his preface, he has been constrained to keep the work within the limits of a textbook rather than let it grow to encylopedic size.

We can recommend the book to all who are interested in this fascinating and eminently practical branch of medicine and biology.

KLINISKE LINSESTUDIER. By HAROLD G. A. GJESSING. Drammen, 1920.

THIS brochure comprises 355 pages of Norwegian text and is a supplement to the May 20 number of the *Norsk Magazin for Laegevidenskaben.* The work consists very largely of tabulations of cases. The Gullstrand lamp with which the studies were made is described. There is a brief section on the normal crystalline lens. Cataractous affections are considered from numerous viewpoints and the author inserts his personal records which occupy over half the book. Other aspects of the study of the lens such as the earliest appearance of cataract, localization of cataract, graphics, tonometry, etc., complete the volume. There is a brief summary of the contents of the book with a bibliography of over 400 references.

CARE AND FEEDING OF INFANTS AND CHILDREN. A Text-book for Trained Nurses. By WALTER REEVE RAMSEY, M.D., Associate Professor of Diseases of Children, University of Minnesota; Associate Visiting Physician to the University Hospital; Visiting Physician to St. Paul City and County Hospital; Medical Director St. Paul Baby Welfare Association, etc. Including Suggestions on Nursing by MARGARET B. LETTICE, Supervising Nurse of the Baby Welfare Association, St. Paul, Minn. 123 illustrations. Second edition revised. Philadelphia and London: J. B. Lippincott Company, 1920.

THE second edition of this book has just appeared in which child welfare forms an important part. The scope of the book remains the same as the first edition. It is profusely illustrated, having 123 illustrations. Several of these could be omitted, as for example No. 119 which is the steam tent, and now discarded by most pediatrists. Also the expression "phthisical" is not seen in modern literature.

There are many practical points, and the book throughout is very instructive. The chapter on the Brain and Central Nervous System is exceptionally good. The statement on page 249 that "clothing can convey poison for years and reproduce the disease 'scarlet fever" can be challenged.

The book is well printed, well bound, and has an exceptionally good index.

AN INDEX OF SYMPTOMS, with Diagnostic Methods. By RALPH WINNINGTON LIFTWICH, M.D., Late Assistant Physician to the East London Children's Hospital; Author of "Tabular Diagnosis," etc. Seventh Edition Revised by H. N. Warner Collins, B.Sc., M.R.C.S., L.R.C.P., Radiographer to the Putney and the Chiswick Hospitals; Deputy Radiographer to the Evelina Hospital; Late Resident Medical Officer, Chester Bequest Hospital, S. W.; Demonstrator in Physiology to the University of London. New York: Wm. Wood & Company, 1920.

THIS book, though not apt to strike one at first glance as very important, is really one that once tried will ever thereafter be found indispensable to the man called upon to diagnose a puzzling case. Its conception and execution stamp the author, whose untimely death is to be deeply regretted, as a true genius, and its survival through six editions affords evidence that its worth is appreciated. The book conducts the physician along the same path he must follow when in the presence of his patient, namely, from the symptoms to the disease, and in many a puzzling case it will give the clew that will lead the examiner to a solution of the diagnostic problem before him.

The final preparation of this seventh edition was entrusted to Dr. Collins, who has brought the work well up to date. It is a book that cannot fail to be of assistance to the practitioner—old as well as young.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Twenty-first Annual Meeting, Held in Philadelphia, May 7 and 8, 1920.

Second Session—Friday Afternoon, May 7.

DR. THOMAS F. REILLY, VICE-PRESIDENT, IN THE CHAIR.

Report of 1,000 Heart Patients Subjected to Complete Examination with Important Therapeutic Results.—Dr. LOUIS F. BISHOP of New York City read this paper, showing a number of electrocardiographic tracings. (See page 508.) In commenting on the electrocardiograms he said that the senile heart reacted well to continuous use of small doses of digitalis, though in this type the electrocardiograph sometimes showed interruption of the conductivity in one of the branches of the auriculoventricular bundle. In all cases examined, the Wassermann test was made, blood and urine analysis were done and polygraphic tracings made. The *x*-ray tube was used at a point 6 feet away from the center of the level of the third rib. In cases of heart block the tracing showed the auricle and ventricle beating independently. In premature contraction the auricle or the ventricle contracted out of place. In paroxysmal tachycardia there was a very rapid rate. In auricular flutter the auricle was beating 200 to the minute. In auricular fibrillation the ventricle beat was irregular and rapid. In sinus arrhythmia an irregular spacing of the beats was shown. When analyzing the true nature of the heart beat it was found to consist of three effects. First the auricle contracted, then the ventricle contracted, but the ventricle could not move the fluid suddenly; the actual ventricular work was the third phase and was represented by the T-wave in the electrocardiograph.

Endocrinology of the Heart.—Dr. THOMAS E. SATTERTHWAITE of New York City presented this communication. (See page 510).

The Treatment of Cardiac Arrhythmia.—Dr. JAMES M. ANDERS of Philadelphia read this paper. (See page 512).

Dr. ROSS V. PATTERSON of Philadelphia said that he could find nothing in these papers with which he was not in entire agreement. He could not speak from as large an experience as Dr. Bishop with his 1000 cases. They had maintained at the Jefferson Hospital a heart clinic for 10 years and had installed the electrocardiograph three years ago. This was used in the wards and private cases. The value of electrocardiographic methods needed careful estimation. There was a tendency to exaggerate the value of every new method and to give it undue importance, while discarding older methods, but there was no doubt that the electrocardiograph had great value in positive findings. In negative findings it often failed. Its use often gave a clue as to the prognosis and helped in the diagnosis between myocardial and nerve lesions. Its use made the work more exact in disentangling conditions which otherwise one would not have been able to identify. Arrhythmia was merely a symptom, and symptoms indicated lesions. The lesions were important as they affected the ability of the heart to perform its work. To treat arrhythmia as such was a great mistake. Dr. Anders had pointed out the underlying factors of this condition. The profession should deplore the excessive use and misuse of digitalis. Wrongly used it did more harm than good, wonderful as it was when properly used. Electrocardiography offered a wide field for investigation. The shortening of the period of conduction of the heart in hyperthyroidism was an example. Studies had been made of this but without satisfactory result. In hypothyroidism there was a tendency to sinus arrhythmia and extrasystoles. A definite relation was shown to exist between the thyroid, adrenal, and hypophyseal secretions.

Dr. H. C. GORDINIER of Troy, N. Y., asked in regard to the use of digitalis whether the massive doses as advised by Eggleston had been tried in the series of cases here presented; he also asked whether the case which presented ventricular fibrillation was one of angina pectoris or possibly thrombosis of a branch of a coronary artery. Ventricular fibrillation was sometimes suddenly induced by the intravenous injection of strophanthin in hearts already under the influence of digitalis. What percentage of the cases here presented had for their etiology syphilis? Extrasystolic arrhythmia, it seemed to him, might be divided from the viewpoint of prognosis into extrasystoles with or without continuous clinical alternation, preceding and following the ectopic beats. Extrasystoles without clinical alternation were of no serious import, whereas those always associated with alternation were of grave prognosis, indicating severe myocardial damage.

Dr. G. KIRK of Troy, N. Y., said he would emphasize the necessity of rest in the treatment of cardiac disease and of arrhythmias with failing heart muscles. Heart lesions were very responsive to rest treatment. Putting the patient at rest overcame heart failure, but this must be for a long period of time, not merely to overcome the acute tension, but for four or five months, if necessary, to give the heart muscle real benefit from the rest.

Dr. A. E. ROUSSEL said that when he was on the medical advisory board he had quite a few cases of tachycardia that had probably been induced by the use of thyroid extract. In two cases in the hospital the patients were found taking thyroid extract. Quite a number of cases of persistent tachycardia might be due to increase of secretion from this gland. In conjunction with Dr. Pfahler he found that the intensive use of the *x*-ray to the gland in Graves' disease had produced cures by causing partial atrophy, andthus modifying the secretion of the gland. Another point of importance was that of ocular pressure. Ashner noted that in most normal individuals pressure on the eyeballs caused a slowing of the pulse rate up to 10 beats to the minute by vagus inhibition. This cardiac inhibitory reflex might be considered as the bilateral group of cells in the medulla at the level of the nuclei of origin of the vagi and when the tonic action constantly excited through this center was increased, cardiac inhibition resulted. The speaker said he had been much interested in this subject and for the past several years he had applied this method in the examination of all his heart cases and found that even in those cases where no apparent reduction in frequency was effected, and in a few cases where it was increased, in a majority of instances this pressure exercised for about two minutes would not only accentuate existing organic murmurs, sometimes to a marked degree, but would also bring out a previously unsuspected murmur. On the other hand, functional murmurs would seem to diminish in intensity or entirely disappear. This test was, Dr. Roussel believed, original, was easily made, and merited recognition.

Dr. E. E. CORNWALL of Brooklyn cited a case of paroxysmal tachycardia which showed an interesting feature. The patient, a woman of about fifty-five, who had a mitral leak of long standing which was well compensated, came to his office in the midst of an attack of paroxysmal tachycardia. The attack was arrested by the patient holding her breath for a few seconds on a sharp order, and then suddenly releasing it. The finger on the pulse at the time of the cessation of the attack was able to appreciate the fact that the pulse rate did not resume the normal immediately, but only after an interval of a few seconds, during which the pulse, while rapidly diminishing in rate, was absolutely irregular.

Dr. THOMAS F. REILLY of New York said that a drug sometimes useful in the treatment of symptoms was the fluid extract of cratægus. It was a safe drug and acted efficiently. Another point was that in severe tachycardia, after two or three attacks, this would become worse. It might be a sign of approaching dissolution. Cyanosis was present. Large doses of codeine or morphine should be prescribed in these cases.

Dr. BISHOP, in closing, said that he enjoyed hearing Dr. Satterthwaite's paper. He meant to try his experience with pituitary, it was very suggestive, and the extract might activate other remedies. Dr. Anders' paper was very complete and covered many points so that it was almost impossible to discuss it entirely. One point of therapeutic value had been learned from a country physician who had a patient, a very old gentleman with complete heart block attacks and syncope.

He was put on continuous small doses of chloral and he got along all right, with 15 grains daily. A premature contraction was often diagnostic of irritable ventricle, which was contracting out of place. The optimal ventricular rate in fibrillation was 90 to the minute. Many physicians pushed digitalis too far. With a pulse of 90 these patients got along all right. Many patients were killed because the physician did not reduce the digitalis. It was hard to know what to compare tachycardia with, except asthma. There were never two asthma cases alike. Attacks could be stopped with all kinds of queer things. Each case was a law unto itself. Alternation of the pulse was due to failure of the peripheral control of the circulation. The electrocardiograph did not show it but the polygraph did. He had never heard a paper which treated the subject as well as did that of Dr. Anders.

Dr. SATTERTHWAITE, in closing, said that he would refer to the statement of Dr. Bishop as to continuous digitalis medication. He thought that digitalis might be continued for years. One might reach the point where one did not need to give it any more. It might take a long time, but digitalis contracted the heart, which got smaller and smaller under its use. Dr. Cornwall had spoken of strophanthus. One could use it for very quick action while one was waiting. In reference to the electrocardiograph and the polygraph, he thought Dr. Patterson rather overestimated the results. The electrocardiograph gave one the actual condition, but the polygraph did not. If one had to depend upon one only, one would use the polygraph, but it was better to have both. The *x*-ray orthogram was very important. Prognosis was a difficult question, it depended upon factors over which the physician had no control whatever. The patient might go away and take up smoking or get indigestion with dilatation of the stomach, and there were many other dangers to be considered. One point might be mentioned in regard to cardiac disease in children. The treatment was by rest, and they should be kept in bed for months, several months, with little medication, and very good results would be obtained. In anginal conditions radiant light applied to the chest stopped the pain and the patient felt better.

Dr. J. M. ANDERS, in closing, said that he had been interested in Dr. Satterthwaite's remarks in regard to exophthalmic goiter associated with hypothyroidism. One sometimes lost sight of this fact to which he had referred in the Osler Anniversary Volume. In such cases thyroid extract was of great service, but one must be certain by studying the basal metabolic rate that hypothyroidism was present. He had seen cases of hyperthyroidism in which the *x*-ray diminished the thyroid secretion and also diminished the heart rate, even in cases with massive enlargement of the thyroid gland. He said his method of giving digitalis was by massive doses. He got his best results this way and stopped when the pulse dropped to 90 or toxic symptoms developed. For cardiac weakness following influenza there was nothing so good as physical and mental rest, if one could induce the patient to take it. Prolonged rest was more effective than drugs. He prescribed cardiac tonics such as arsenic, nux vomica, and iron, rather than stimulants. He put decompensated patients to bed and restricted the diet to fluids for a time.

Dr. REILLY asked Dr. Anders if he had ever seen fatal results from the use of digitalis.

Dr. ANDERS said that in two instances at least digitalis had apparently been the cause of death, but in these cases the disease was far advanced.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 15, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged in cooperation with the Section on Ophthalmology.

The Injurious Effects on the Eye of the Various Toxemias.—Dr. W. HOLLAND WILMER of Washington, D. C., delivered this address by invitation. He stated that in an exhaustive symposium before the Southern Medical Association, in 1917, the subject of oral sepsis was discussed in its relation to the digestive apparatus, the anemias, thyroid deficiency, arthritis, the cardiovascular system, and the nervous system, but the relation of the eye to oral sepsis was not set forth in this symposium, although from the standpoint of economics and human happiness the eye should be considered one of the most important organs in such discussions. In addition the ocular tissues presented great advantages for observing pathological changes during inflammatory processes. According to the present conception of focal infections, the bacteria from a distant focus, circulating in the blood or lymph canal, found a location that suited their taste and there they built a new home. Whether the new habitat was in the gallbladder, the kidneys, articulations, the endocrines, etc., or in the eye, depended upon different circumstances, the bacillary strain, slight injury, a sensitizing effect of some secondary focus, cold, oxygen tension, or other factors with which we were not familiar. It was also conceivable that the toxins—byproducts of bacterial life—might also set up inflammatory conditions in widely separate organs. In his "Ocular Diseases Resulting from Dental Lesions," Dr. Arthur D. Beck said in regard to eye inflammations, "The latter are practically always due to an infection involving the peridental membrane, either in the form of an alveolar abscess at the root apex, or a pus pocket alongside the root. As probably not less than 58 per cent. of all persons having teeth present one of these conditions the mouth is probably the most important offender in cases of secondary eye lesions." As the age of the patient advanced the amount of crown and bridge work and the number of devitalized teeth usually increased, so that the mouth as a source of sepsis had to be examined with the greater suspicion. The deeper root infections could only be revealed by the *x*-ray. Oral sepsis could be held directly responsible for iritis, disseminated chorioretinitis resembling retinitis pigmentosa, and especially large serous exudations in the choroid, simulating, or actually causing, detached retina. In the light of our new views it was not at all surprising that a relatively large proportion of eye lesions were now found to be of a tuberculous nature. Tuberculosis was as impartial as oral sepsis; there was no tissue of the eye not influenced by the tuberculous process. But, in the writer's experience, it showed a special predilection for the cornea, the retina, and the uveal tract. The retina afforded the best opportunity for studying with the opthalmoscope the various pathological changes. Here one could also detect slight focal reactions to the tests.

The essayist discussed a type of retinal inflammation, usually of tuberculous origin, that was of deep interest and great economic as well as human significance, namely, recurrent hemorrhages of the retina in young adults, chiefly males. He reported an illustrative case in detail. This case, he said, was interesting because of the unusual good health of the patient, the long continuance of the trouble, the negative reactions to several von Pirquet tests, the positive reaction to the subcutaneous injection of tuberculin, and the final improvement as the result of the therapeutic administration of tuberculin. Recurrent retinal hemorrhages, however, were not all of tuberculous origin. He had seen the condition in a patient suffering from constipation and a bad pyorrhea alveolaris. Upon the removal of the source of infection, within seven months, the vitreous entirely cleared up, leaving normal vision and there had been no return of the hemorrhages. Another type of toxemia discussed was that which could follow antityphoid inoculations. A careful study of this type of toxemia was of great importance owing to the far-reaching economic and medical values of the inoculations themselves, and also because it was not recognized generally that there was a possibility that affections of the eye might occur after the inoculations. Several such cases were reported in the literature, to which the essayist added one coming under his personal observation. It was difficult to explain why this immunizing treatment was followed by eye lesions in some cases and not in others. However, one might conceive that the occurrence was explained by the varying age of the solution, the general lowered resistance of the

subject at the time, and the sensitization of the eye tissues by some preexisting toxemia. In the case reported a long standing sinusitis furnished the sensitizing medium. In reviewing the literature of the toxemias in the light of his own experience, Dr. Wilmer said there were some facts that stood out with special prominence. Dr. Barker's advice to the internist was equally valuable for the opthalmologist in his search for the cause of some of the obscure eye infections. Dr. Barker said: "In looking for focal infections I think the practitioner will be helped if he remember that most often in children the primary focus is in the tonsils or adenoids, and that in older people it is more often in the teeth, paranasal sinuses, or gallbladder." However, the source of infection was often a mixed one, such as a combination of teeth and tonsils, tuberculosis with cholecystitis, etc. Certain portions of the intestinal tract, with its abundance of lymphoid tissue, served as an important source of toxins. Whether this was primary or secondary to sepsis in the mouth or throat, it must be investigated in every case. No part of the eye was immune from the possibility of damage from some toxic process in a different part of the body. It was the writer's conviction that improved laboratory methods would show that the relationship between lenticular opacities (even in older people) and some focal infections was a closer one than was now believed to exist. Pathological conditions of organs of internal secretion, though secondary to some distant source of toxemia, had an important bearing upon some types of inflammation of the uveal tract. In some cases of retinal hemorrhage in people over fifty years of age, some focus of infection, as the teeth or tonsils, gave an ophthalmoscopic picture resembling an arteriosclerotic process. But the hemorrhage and white degenerative plaques cleared up remarkably after the complete removal of the general arterial hypertension. It was very necessary for the ophthalmologist to be able to interpret in a general way the *x*-ray findings in regard to the teeth so that he might cooperate with the dental surgeon by advising the best method of procedure in dealing with certain types of oral sepsis. For example, when there was an apical abscess at the root of a surviving molar that was being used as a pivot for bridge work, the ophthalmologist must be able to decide, not only that the eye lesion was sufficiently serious, but that the picture was sufficiently clear cut to warrant the sacrificing of that important tooth. It was well to remember that root resection could be employed in apical abscesses in the eight upper central and six lower central teeth. In adults the only reliable test for ocular tuberculosis was the subcutaneous injection of tuberculin, preferably old tuberculin. The temperature should be taken every two hours for two days previous and also an *x*-ray of the lungs in all cases. It was the part of wisdom to make the first injection small. This was particularly true of acute lesions involving the retina or choroid. The necessity of giving very small curative doses at the start was emphasized by all ophthalmologists of experience. In most cases therapeutic injections of tuberculin were very efficacious when accompanied by the proper régime and hygiene. In typhoid inoculations in civil practice it was not wise to give the inoculations as long as there was any evidence of the existence of any focal infection. A clinical fact of interest was that often nonsyphilitic lesions of the uveal tract were favorably influenced by antisyphilitic treatment. Also long protracted lesions were helped by the administration of the extract of certain glandular organs. In some of the writer's cases with oral sepsis there was increase in the protein content of the spinal fluid without other detectable cause for it. This suggested the possibility that toxins might enter the nervous system either by way of the lymphatics or through the blood stream. There were certain principles of therapeutics that assisted in the rehabilitation of injured tissues; eradication of all toxic sources and stimulation of nature's method by bringing an increased number of leucocytes to the zone of activity. This might be accomplished by hot applications, and at certain stages of the inflammation dionin and subconjunctival injections of normal salt solution. It was obvious that nearly all involvement of the anterior portion of the uveal tract would require the local use of atropine. In case of retinal hemorrhage accompanied by long coagulation time the use of lime salts was indicated. In all toxemias the gastrointestinal tract should receive attention both in regard to diet and therapeutics; it was important that these measures should be applied while the source of the toxin was under investigation.

Dr. NELLIS B. FOSTER said that Dr. Wilmer had touched upon a number of questions that were not only interesting to the ophthalmologist, but equally interesting to the internist. Some of the questions which Dr. Wilmer had been forced to pass over rather cursorily were of very profound significance, and in fact went to the roots of questions of pathology. This question of focal infection was one that was very much to the front at the present time, and was one in which they were all primarily concerned. Dr. Foster then called attention to certain points by way of caution in deductions based on evidence that at first sight seemed quite conclusive. All knew how frequent focal infections were. Beyond a certain period of life it was doubtful if any of us escaped and so we must postulate a second factor, namely, individual predisposition, since some individuals maintained robust health in spite of these known foci. Dr. Foster said he did not wish to convey the impression that the expression predisposition was used in a scientific way at all. His meaning, he said, was best brought out by Dr. Wilmer's remark about antityphoid inoculation in respect to the eye. It did not require any stretch of imagination to think that in certain individuals antityphoid vaccination might give rise to certain demonstrable lesions in the eye. As was known, the great majority of persons inoculated with antityphoid vaccine showed only slight and transitory symptoms, a little fever, malaise and slight muscular stiffness. But there was a small minority in which quite a definite train of graver symptoms developed. To one of these types he wished to call attention because so far as he knew only a few cases had been seen, and he himself had seen a number. These were cases that showed a type of reaction that might be called purpuric. The manifestations in these individuals were first a purpuric rash such as one saw typically in cerebrospinal meningitis. The rash appeared twelve hours after inoculation, and was associated with fever and might be associated with hemorrhages. In some cases there were only a few hemorrhagic spots on the skin, along with hemorrhage from the kidneys or intestines and epistaxis. If hemorrhage occurred in the skin, kidneys, or intestines, it stood to reason that it might occur in the central nervous system, and he had seen one case in which it did occur, causing a transverse myelitis and a number with meningismus. We had here again the same factor to which he had called attention, and which must be constantly remembered, namely, that there were exceptional individuals with unusual predispositions. These cases of atypical reaction, Dr. Foster said, he had seen in the army, and they were all apparently healthy individuals; he had examined them and found no evidence of disease. This brought him to the second point he wished to mention, which was that these hemorrhages in the retina or elsewhere in the body were due either to changes in the blood vessels or changes in the blood. We knew at the present time no other cause for hemorrhages, except changes in the endothelium of the arteries and changes in the blood itself, for example, in infectious diseases there was a proneness to embolism or thrombosis, as well as to hemorrhages. These hemorrhages that Dr. Wilmer mentioned as occurring in the ages of young men could be explained in no other way than that just offered. Cerebral hemorrhages were not at all a rare thing, even in children, where there could not be demonstrated any such disease as syphilis, which was thought of as the etiological factor in degeneration of the vascular system. It was thought such hemorrhages were explained by the effect on the blood vessels of past infectious disease, perhaps a trivial disease of childhood. If, as sometimes happened, these cerebral hemorrhages were so severe as to cause death it seemed not at all an incorrct deduction that they might occur in the small vessels of the eye because the eye is in fact a projection of the central nervous system. One other point which Dr. Foster discussed was in regard to the treatment of uveitis with thyroid. He said he

had had occasion to look into that subject. A good many ophthalmologists seemed to believe that many disturbances of the eye were of endocrine origin and thyroid extract was recognized as the one mode of approach in the treatment of uveitis. He had been somewhat puzzled over that fact and thought that the supposed benefit of that treatment was due to other causes than that suggested. Uveitis was a disease that progressed in waves, and the period of improvement might conceivably be coincident with the administration of thyroid extract. Another reason might be that small doses of thyroid were stimulating and brought about the same improvement that might be brought about by a change in climate, stimulating the appetite, increasing body weight, and rejuvenating in the larger sense some dormant functions, so that the improvement of uveitis which occurred in individuals who were subnormal in health could be explained on those grounds. While improvement in uveitis might occur under the administration of small doses of thyroid it was inconceivable that large continued doses of thyroid extract should cure the disease. The assumption of a relationship of some other obscure diseases of the eye to other endocrine disturbances so-called seemed to him simply a mask for our ignorance. He would like to know what Dr. Wilmer thought about it.

Dr. WARFIELD T. LONGCOPE said he thought they had all been greatly interested in Dr. Wilmer's presentation. Some of the things that Dr. Wilmer had said were to a certain extent new to him. He had been particularly struck with the reactions that occurred in individuals who received antityphoid inoculations. The whole problem of disease in organs distant from the focus of infection was receiving such great attention that almost everybody knew something of it, but there was still much that we did not know about it. It was quite true that most individuals in the course of their lives had focal infections which they carried for many years, and perhaps a large proportion of these individuals suffered no discoverable effect from the focal infection, but a number did, and there was evidence from day to day that these infections were responsible for lesions in distant organs, as the joints, the kidney, the eye, etc., and hence we must assume that it was true that focal infections were a latent source of danger to a certain proportion of individuals who carried them. It was therefore good prophylaxis to remove as far as possible the foci of infection when they occurred, for where they were discovered they did no good and they might do harm. Besides the cases of definite infection there were some people with an indefinite condition; they merely did not have good health. They might be slightly anemic, might suffer a slight loss of weight and might not be as active as ordinarily, but nothing definite could be found. If, however, one analyzed these symptoms they might be found to be due to chronic infection or even to a mild tuberculosis. The removal of the teeth and any apical abscesses might clear up the symptoms due to the infection, and, again it might not. Even if several foci of infection were removed one could not say confidently in every instance, or even in the majority of instances, that the correct one had been removed. Perhaps in the future we might gain the knowledge which would enable us to locate and remove the exact focus but today it was impossible.

Dr. ROBERT G. REESE said they had all seen miraculous recoveries, especially in tuberculous cases, and he had hoped that Dr. Wilmer would have mentioned some of his failures, as his own had been so numerous. The relation between toxemias and diseases of the eye was a complex one, and unfortunately the clinical picture was by no means characteristic. We were apt on account of our wonderful successes to forget that there were other etiological factors in the diseases of the eyes and adnexa, as was shown by the case of a young woman who had had her tonsils enucleated, a few teeth extracted, and the intestinal tract vigorously treated. She presented the typical picture described by the older writers as "lippitudo", that was chronic blepharo conjunctivitis, madarosis, and hypertrophy of the tarsal conjunctivæ. By digital expression of the meibomian concretions, the application of a two per cent. nitrate of silver solution, and the instillation of one-half per cent. nizin, with massage with an antiseptic salve, she was making a fair recovery. He believed that all diseases of the uveal tract were either of septic or toxic origin, but the successful elimination of these agents was very perplexing. He then cited in detail the case of a woman who had had uveitis for eight years, in whom removal of the teeth and tonsils, tuberculin injections, antiluetic treatment and an iridectomy had failed to effect a cure. He reviewed the various laboratory reports and the report of the roentgenologist to show how complicated the problem of locating the source of infection might be, and how ineffective all methods of treatment sometimes were.

Dr. GEORGE H. BELL said he had enjoyed very much indeed Dr. Wilmer's paper and the message he brought in regard to the effects of toxemia on the eye. The paper was most valuable, for Dr. Wilmer's experience had been very extensive, as he had been alive to the situation. Toxemia from food intoxication, bad teeth and tonsils was the most important subject before the medical profession today. Dr. Bell recalled that before the meeting of the American Medical Association last June he had made the statement that a dirty mouth was one of the greatest menaces of the human race. The late Dr. Osler said recently that bad teeth were causing more ill health and misery than strong drink. This subject was by no means new to all of them. From time to time during the past ten years, he had called the attention of the profession to the fact that modern dentistry was producing more disease than any other cause. His first paper on this subject was read here before the Academy in 1910. As to the causes of toxemia and its effects on the eye, if we excluded syphilis and gonorrhea, he believed that all the eye conditions that we saw, were caused directly or indirectly by focal infections, and the three most potent ones were bad teeth and tonsils and food intoxication, all of which could produce a general toxemia, which might have a local manifestation in the eye, in the form of uveitis, choroiditis, iritis, episcleritis, optic neuritis and keratitis. Dr. J. Herbert Parsons, in 1908, said in his pathology on the eye, that oral sepsis was an undoubted cause of irido-cyclitis, owing to the absorption of toxins into the circulation. Dr. Bell said he recognized that there were a lot of things that we could not prove in regard to the doctrine of focal infections and toxemia. But when he had case after case of iritis, choroiditis, episcleritis, etc., get well after removing the foci of infection; then in the absence of positive proof the process of elimination was good enough for him. There was one case which Dr. Bell spoke of, a case of bilateral papilloedema with nine diopters of swelling of the nerve head, in a man 34 years of age, with a blood pressure of 200. The neurologist who saw him in consultation thought that in all probability the patient had a tumor of the brain. On clearing up his focus of infection and his profound toxemia this man recovered a vision of 20-50 O. U. His blood pressure fell to 140, and he had returned to work. He had shown his patient here at the Academy two years ago. He believed that an endogenous septic endophthalmitis might occur in any eye at any time, whenever there was present in the body a focus of infection from which toxins or bacteria could escape into the circulation. Why the optic nerve should be affected in some cases of toxemia, the uvea in other cases, the cornea in some, and the vitreous in others, Dr. Bell said he could not state, nor was he able to say how it was brought about. We must all admit, however, that toxemia might result from chemical changes in the intestinal contents and that the absorption of bacteria and their toxins did take place, and that the blood stream was the carrier of the infection.

Dr. JAMES O'DWYER said he wished Dr. Wilmer had given them some practical points to guide the ophthalmologist. He thought the diagnosis of tuberculosis could be safely left to the clinician. He did not use the von Pirquet test but preferred the intradermal test with old tuberculin. He felt that the von Pirquet test was not reliable. What was true of the diagnosis of tuberculosis was also true of syphilis. A point of importance was that in all focal infections of the eye,

whether from the teeth or the tonsils, there was always pus under pressure. When the pus was under pressure the bacterial toxins were forced out into the system. A focus of infection in the teeth alone never caused a focal infection unless there was an apical abscess with pus under pressure. The bacterial toxins when the pus was under pressure were rapidly absorbed into the system and produced sensitization. He believed the eye or some locality where the blood changed to lymph was a point of special selectivity for the lesion. He thought the filtrate passed on at such a point and the proteins were retained and that led to proteolysis. Again, one found that it was not the soft mushy tonsils that became infected but the small sclerotic ones in which the pus was held under pressure. He had tried to make studies of the spinal fluid but had found no basis on which to work because in the presence of a foreign protein even a normal spinal fluid changed somewhat. A point brought out by Dr. Knapp was that the toxemia of acute infection, such as tonsilitis, might be followed by albuminuria, due to disturbance in the secretion and retention of toxic products, and he had known instances in which a focal infection in both eyes was associated with the typical picture of nephritis. He had also seen this in measles, chickenpox, and typhoid fever.

Dr. WALTER B. JAMES said that Dr. Wilmer's delightful paper presenting this timely subject in so clear a way had done a service to the whole profession of New York, not only to those practising in the field of ophthalmology but to everybody charged with the responsibility for the care of the sick no matter what part of the body might be at fault. Whatever specialty we might be practising we had come to realize that focal infections, and indeed the other intoxications, had a far reaching significance. While the expectation of human life had increased very greatly during recent years, and entirely through the efforts of the medical profession, it was generally admitted that this increase had been brought about by improvement in the mortality rate of infancy and childhood rather than because of any well marked impression made upon the death rate from the diseases of later life. Dr. Wilmer's paper suggested quite a different point of view towards these later diseases than that which had obtained during the past thirty-five or forty years and before. It had been customary to assume that when a man of middle life had a disease, for instance, of the kidneys or of the heart or of the joints, and when by the use of instruments of precision and careful diagnostic methods we had located the lesion and told him that his symptoms were due to Bright's disease, hardening of the arteries, or sclerosis of the heart muscle perhaps, and had made a prognosis telling him how long he had to live, we had been wont to feel that we had done our duty. Today, fortunately, we were taking less interest in the minutiæ of physical diagnosis and were giving more attention to the study of the ultimate origin of the disease in the individual case. Physicians used to ask a man of fifty or sixty who was suffering from Bright's disease or other organic trouble what his father died of. When he replied, "dropsy at the age of sixty," the physician would say, "this is about what you have to expect." We used to ask a man if he was a hearty eater and if he replied that he was, we ascribed his trouble to eating too much; if he said that he was a very light eater, we perhaps attributed it to too little nourishment. We asked him if he was a hard worker and generally his wife answered that her husband had always worked himself to death, and then we said "no wonder you have a chronic disease." As a matter of fact, it was a matter of much doubt whether people did get Bright's disease or heart disease because they worked too much or too little, or ate too much or too little, and we were not at all sure now even that alcohol had played as important a part in the causation of diseases of middle life as we had once thought. Therefore this modern conception of medicine and diagnosis and its purpose as presented by Dr. Wilmer this evening, was intensely interesting and applied to every branch of medicine and to the diseases both of the body and the mind, for even in mental diseases it was becoming more and more clear that the body, and the entire body, should be searched for causes of the malady. There was probably a definite cause for every kind of disease and we should demand to know this cause if it was discoverable by any means at our command, and if we could not discover it, we should honestly admit that the fault was our own.

Dr. James said that one of the great difficulties in treating diseases of middle life was that we were apt to find that they were not simple but very complicated. The late Dr. Jacobi, in his delightful way, once told the speaker that he preferred to treat children rather than adults because almost invariably a child had but one disease at a time, whereas adults rarely had only one. The profession should accept the principle that when an individual manifested any departure from the normal in any function, the making of a diagnosis in the old fashioned sense was only the beginning; that there was a definite cause for this disturbance and that this cause should be sought by every means that medical science offered. Dr. Reese in his discussion, regretted that Dr. Wilmer said nothing of his failures. Dr. Wilmer, like the rest of us, was human and of course he had had failures. Like the rest of us he had had at his command only such knowledge of physiology, pathology, and causation as medical science of today offered, and while he had pointed out to us that many cases of serious organic diseases of the eye had a remote physical cause in some part of the body, perhaps far distant from the eyes, yet there were doubtless other causes of these same eye lesions which were not accessible to us today but which would certainly be accessible to the physician of the future, if the profession continued to take the broad view of medical science that it always had taken. There were perhaps causes other than focal infection and other intoxications, causes that we had not yet dreamed of, but some day they would be known and understood. Future studies and the lapse of years would probably open up new and wonderful vistas for medicine, and with these the ability to either ward off or cure or ameliorate a good many of the diseases of middle and later life which had hitherto proved so obstinate. Of course chronic rheumatism, as well as eye lesions, and probably a good deal of vague ill health without definite local complaint, were caused by foci of infection in the teeth and tonsils, but we had all seen plenty of cases of this type where the disease went on just the same after the teeth and tonsils were removed. Dr. James said he had seen a number of cases of very obstinate rheumatism of the rheumatoid arthritis type, in persons who had completely recovered from a pulmonary tuberculosis, usually with some cavity formation and in whom no local cause could be found in the teeth or in the tonsils, and in whom it seemed at least possible that the intoxication came from a healed cavity at the apex of the lung which gave few or no symptoms of the ordinary type. Then there was the alimentary canal, especially the colon and the ileocecal valve, offering possibilities of ill health from intoxication, but this was a chapter which was always vague and upon which a great deal of work still remained to be done. Dr. Wilmer's paper was interesting then to those practising in every field of medicine, pointing out as it did, defects in the teaching of diagnostic medicine and emphasizing the need of searching more diligently for the cause of disease in each individual case. The medical profession of New York was deeply indebted to Dr. Wilmer for his willingness to come to New York, especially at a time when travelling was no simple matter, in order to lay before it the results of his vast experiences and his own philosophical reflections upon these experiences.

Glycorrhachia and Lethargic Encephalitis.—Dopter has made a discovery which may prove of value in the diagnosis of lethargic encephalitis. When somnolence appears, the percentage of glucose in the spinal fluid is found to be increased. Professor Netter has confirmed the discovery and its value, for thus far the sign has been constant and has been absent in other affections tested. In meningitis we find lymphocytosis and increased albumin, which are absent in encephalitis. But unless we can discover the reason for the increase of sugar the test will lose some of its force.—*Gazette des Hôpitaux.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Texas State Board of Medical Examiners.

November, 1919.

ANATOMY.

1. Name the ligaments of the ankle joint.
2. Bound Scarpa's triangle, and name the vessels and nerves in it.
3. Names the muscles attached to the great trochanter of the femur.
4. What are the anterior and posterior boundaries of the axilla, and what arteries and nerves pass through it?
5. Name the ganglia connected with the fifth pair of cranial nerves.
6. Trace the cerebrospinal fluid from the lateral ventricles to the spinal canal.
7. Name the ductless glands.
8. Describe the portal system.
9. Name the branches of the subclavian artery.
10. What arteries supply the heart with blood, and where do they originate?

HISTOLOGY.

1. Name and define the stages of mitosis.
2. Classify connective tissue.
3. Describe a lymph node.
4. Of what organ are Hassall's corpuscles characteristic? Describe one.
5. Name the cells found in the bone marrow.
6. Describe a lobule of the liver, giving in detail the mode of blood supply.
7. Describe the cortex of the adrenals.
8. Draw diagram of a vertical section of the duodenum.
9. Draw diagram of a small bronchus.
10. Describe a spermatozoon.

PHYSIOLOGY.

1. Nerve mechanism of mastication.
2. Physiological properties of protoplasm.
3. What are the three fundamental functions of cell life?
4. What are the effects which would follow severing the third nerve?
5. What would be the result of the removal of the whole or a large part of the cerebellum?
6. What two things cause the establishment of respiration at birth, and how are they accomplished?
7. What are the functions of the medulla and pons?
8. Describe and give functions of vas deferens.
9. What are the functions of the red and white blood corpuscles, and how many are found in one cubic millimeter of blood?
10. State the branches and their functions which the facial nerve gives off in the acqueduct of Fallopius.

CHEMISTRY.

1. Differentiate between a simple salt and an oxysalt. Give example of each.
2. Write a formula equation showing the action of sulphuric acid on sodium chloride.
3. Give two methods of obtaining nitrogen, and state how it may be distinguished from hydrogen.
4. Mention the objection to lead water pipes. State the kind of water which, when used with these pipes, is especially dangerous.
5. What is the chemical antidote for mercuric chloride, and what is the general treatment in a case of poisoning?
6. What are proteins? From what are they derived? Name the chief proteins.
7. Name and describe the bile pigments.
8. Give the reaction, specific gravity and percentage of cream, of a specimen of normal cow and human milk.
9. Describe the fermentation test and Trommer's test for glucose in the urine.
10. Give a reliable method of the quantitative determination of albumen in nephritic urine.

PATHOLOGY.

1. Give etiology and pathological anatomy of chronic endocarditis.
2. Describe the usual lesion of external anthrax. Give mode of infection and differential diagnosis. How does it produce death?
3. Give the etiology of thrombosis.
4. Give the structure and evolution of the tubercle.
5. What are the differences between typhoid and paratyphoid?
6. Give the blood picture of chlorosis.
7. Describe a hobnail liver.
8. What is meant by cloudy swelling?
9. What is the pathology of angina pectoris?
10. What is the difference between dry and moist gangrene?

ANSWERS.

ANATOMY.

1. The *ligaments of the ankle joint* are: The anterior tibio-tarsal, posterior tibio-tarsal, internal lateral, and external lateral.

2. Scarpa's triangle is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it is the crural branch of the genitocrural nerve.

3. The *muscles attached to the great trochanter of the femur*, are: Gluteus medius, gluteus minimus, pyriformis, obturator internus, obturator externus, gemellus superior, and gemellus inferior.

4. The axillary space is *bounded: Anteriorly*, by the clavicle, subclavius, pectoralis major, costocoracoid membrane, pectoralis minor; *posteriorly*, by the subscapularis, teres major, and latissimus dorsi.

Contents: The axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves.

5. The *ganglia connected with the fifth pair of cranial nerves*, are: Gasserian, ophthalmic, Meckel's, submaxillary, and otic.

6. The cerebrospinal fluid passes from the lateral ventricles, through the foramen of Monro, into the third ventricle, through the third ventricle, through the aqueduct of Sylvius, into and through the fourth ventricle, and into the central canal of the spinal cord.

7. *The ductless glands*, are: Thyroid, parathyroids, thymus, spleen, adrenals, carotid, coccygeal, pituitary, and pineal.

8. *The portal system.*—The veins of the portal system collect the blood from the digestive tract. They form a trunk, the *vena portæ*, which enters the liver and breaks up into small branches in its substance. The following veins form the portal system:

Inferior mesenteric: drains rectum, sigmoid, flexure, and descending colon. It lies to the left of its artery, and passing behind transverse part of the duodenum and the pancreas, and over left kidney, opens into the splenic vein. (The hemorrhoidal branches inosculate with the hemorrhoidal branches of the internal iliac.)

Superior mesenteric: drains small intestines, cecum, ascending and transverse colon. It passes upwards in front and to right of superior mesenteric artery, in front of transverse part of duodenum, and behind neck of pancreas joins the splenic vein at the upper border of the pancreas to form the portal vein.

Splenic: commences in five or six branches in hilum of spleen; these unite to form a trunk which passes below splenic artery behind upper border of pancreas from left to right, and in front of aorta; joins superior mesenteric at a right angle.

The gastric or coronary: a large vein accompanying

coronary artery from right to left along lesser curvature of stomach to cardia, where it reaches esophageal tributaries, and, passing to right behind lesser sac, opens into the vena portæ.—(*Aids to Anatomy.*)

The *portal vein* is formed by the union of the splenic and superior mesenteric veins in front of the right crus of diaphragm and inferior vena cava, and behind the neck of the pancreas. Passes up behind first part of duodenum and then between the layers of the small omentum, behind and between the common bile-duct and hepatic artery, the duct being placed on the right and artery on the left, to transverse fissure of liver, where it divides into right and left branches to corresponding lobes, and also gives an offset to the Spigelian lobe.

Connected with the branch to the left lobe are in front the *obliterated umbilical vein* and behind the *ductus venosus*, the remains of a fetal connection with the inferior vena cava.—(*Aids to Anatomy.*)

9. *The branches of the subclavian artery* are: Vertebral, thyroid axis, internal mammary, and superior intercostal.

10. *The heart is supplied with blood* by the right and left coronary arteries, which arise from the ascending aorta, immediately above the attached margin of the semilunar valves.

HISTOLOGY.

1. *The stages of mitosis*, are: (1) The *prophase*, or stage in which the nucleus is prepared for division; (2) the *metaphase*, or stage in which the nuclear elements are separated; (3) the *anaphase*, or stage in which the daughter nuclei are formed; and (4) the *telophase*, or stage of division of the cell protoplasm.

2. *Classification of connective tissues:* Fibrous, areolar, reticular, lymphoid or adenoid, elastic, fat, cartilage, bone, and neuroglia.

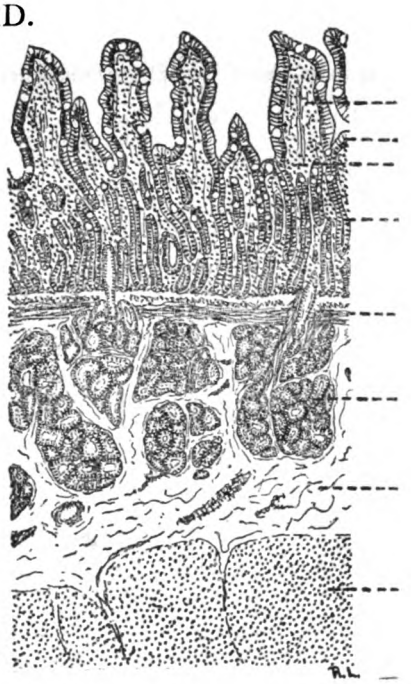
3. *Lymph nodes* are small, oval bodies, surrounded by a capsule which sends septa into the node; both capsule and septa are made of connective tissue. Internally, the node consists of reticular connective tissue and lymphatic tissue. At the hilum, arteries and nerves enter the node, and lymph vessels and veins leave the node. The center of the mass is called the germinal center. The capsule contains a small amount of smooth muscular tissue.

4. Hassall's corpuscles are found in the thymus gland. These corpuscles are oval or spherical bodies which contain epithelial cells concentrically arranged. In the center of these corpuscles the cells are generally nucleated and spherical; the cells in the periphery are non-nucleated and flat.

5. Bone marrow contains the following kinds of cells: Myelocytes, erythroblasts, normoblasts, non-nucleated red cells, myeloplaxes, mast cells, leucocytes, and fat cells.

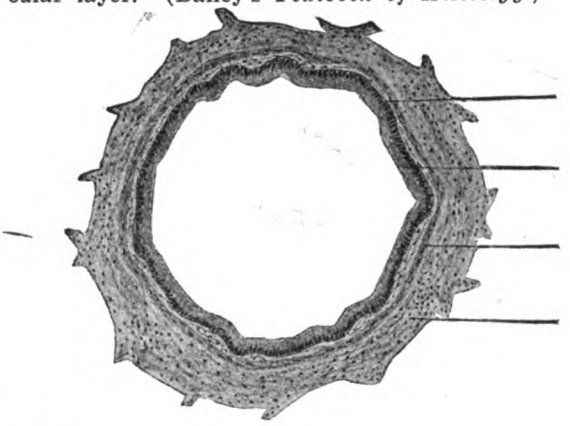
6. A *lobule of the liver* is about 1-20 to 1-12 inch in diameter. It has a darkish red center and a lighter circumference. The center is occupied by an intralobular vein which collects the blood from the capillaries of the lobule, and flows into the sublobular vein, which latter opens into the hepatic vein. Around the lobules are the interlobular veins; these are branches of the portal system; capillaries passing from the circumference to the center of the lobule connect the interlobular and intralobular veins. Between the network of capillaries in the lobule the hepatic cells are packed.

7. The *cortex of the adrenals* "is subdivided into three layers or zones: (*a*) A narrow, superficial layer, the *glomerular zone;* (*b*) a broad middle layer, the *fascicular zone;* and (*c*) a narrow deep layer, the *reticular zone.* The names of the layers are indicative of the shape of the connective-tissue-enclosed compartments and of the contained groups of gland cells. In the glomerular zone the high, irregularly columnar epithelium is arranged in spherical or oval groups. The protoplasm of the cells is granular, and their nuclei are rich in chromatin. In the fascicular zone polyhedral cells are arranged in long columns or fascicles. The cytoplasm is granular and usually contains some or many fat droplets. The nuclei contain less chromatin than those in the glomerular zone. In the reticular zone similar though somewhat more darkly staining cells form a coarse reticulum of irregular anastomosing cords."—(Bailey's *Text-Book of Histology.*)



8.

Vertical longitudinal section of cat's duodenum, showing Brunner's glands. (Larrabee.) *a*, Villus; *b*, epithelium; *c*, stroma; *d*, glands; *e*, muscularis mucosæ; *f*, Brunner's glands; *g*, submucosa; *h*, circular muscular layer.—(Bailey's *Textbook of Histology.*)



9.

Transverse section of small bronchus from the human lung. X 115. *a*. Stroma; *b*, epithelium; *c*, muscularis mucosæ; *d*, fibrous coat.—(Bailey's *Textbook of Histology.*)

10. A spermatozoon is a long, slender body, consisting of a head, neck, body, and tail piece. The head is flattened and oval, and is surrounded by a head-cap. The neck is very short. The body is about the same length as the head. The tail consists of a main segment and a terminal segment. The whole spermatozoon has the general appearance of a tadpole, and is about 60 or 70 microns in length. As a rule only the head and the tail can be observed under the microscope.

PHYSIOLOGY.

1. *The nerve mechanism of mastication.* This consists of a nerve center situated in the medulla, and efferent fibers, and afferent fibers. The *efferent* nerves are the inferior maxillary of the fifth cranial (which supplies the masseter, temporal, pterygoids, mylohyoid, and anterior belly of digastric), the hypoglossal (which supplies the muscles of the tongue), and the facial (which supplies the muscles of the face). The *afferent* nerves involved are the glossopharyngeal, and the lingual and buccal branches of the fifth cranial.

2. *Properties of protoplasm:* "Protoplasm is a semi-fluid substance which swells up but does not mix with water. It is transparent and generally colorless, with refractive index higher than that of water but lower than that of oil. It is neutral or weakly alkaline in

reaction, but may under special circumstances be acid, as, for example, after activity. It undergoes stiffening or coagulation at a temperature of about 54.5° C. (130° F.), and hence no organism can live when its own temperature is raised above that point; it is also coagulated and therefore killed by alcohol, by solutions of many of the metallic salts, by strong acids and alkalies, and by many other substances."

3. *Three fundamental functions of cell life*, are: Growth, movement, and reproduction.

4. *Effects of severing the third cranial nerve:* Ptosis, diplopia, external strabismus, loss of positive accommodation, dilatation of the pupil, the eyeball is slightly more prominent.

5. *Result of removal of whole or large part of cerebellum:* Inco-ordination, loss of equilibrium.

6. *The establishment of respiration at birth is caused by:* (1) The accumulation of carbon dioxide in the blood which stimulates the inspiratory center; and (2) the loss of body heat which (by the cutaneous nerves) stimulates the inspiratory center.

7. The *functions of the medulla oblongata* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of co-ordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

The *function of the pons* is to provide a bridge along which impulses may travel to and from the cerebrum.

8. The *vas deferens* is the excretory duct of the testicle; it is a long, thick-walled tube, and extends from the epididymis up to the external ring, through the inguinal canal and the internal ring, into the abdominal cavity, and to the under surface of the base of the bladder where it joins the duct of the seminal vesicle, the two forming the ejaculatory duct. Its function is to convey the secretion of the testicle to the ejaculatory duct.

9. The *function of the red corpuscles* is to carry oxygen from the lungs to the tissues. *Function of the white corpuscles:* (1) To serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

There are about 4,500,000 to 5,000,000 red corpuscles in each cubic millimeter of blood, and about 7,000 to 10,000 or 12,000 white corpuscles in each cubic millimeter of blood.

10. *The branches of the facial nerve, given off in the aqueduct of Fallopius*, are: (1) *The great superficial petrosal*, which goes to Meckel's ganglion, and supplies vasodilator and secretory fibers to the roof of the mouth, palate, nose, gums, and part of the pharynx; it is also supposed to supply motor fibers to the azygos uvulæ and levator palati muscles. (2) *The small superficial petrosal*, which passes to the otic ganglion; it contains vasodilator and secretory fibers, and is distributed mainly to the parotid gland, and the mucous membrane of the lips and cheek. (3) *The nerve to the stapedius muscle*, which conducts motor impulses to this muscle. (4) *The chorda tympani*, which is vasodilator and secretory to the submaxillary and sublingual glands; it is also the nerve of taste of the anterior two-thirds of the tongue.

CHEMISTRY.

1. *A simple salt* (like sodium chloride) is the salt of a hydracid.

An oxysalt (like sodium sulphate) is the salt of an oxyacid.

2. $H_2SO_4 + 2NaCl = Na_2SO_4 + 2HCl$
and $H_2SO_4 + NaCl = NaHSO_4 + HCl$.

3. *Two methods of obtaining nitrogen:*
(1) By heating ammonium nitrite:
$NH_4NO_2 = 2H_2O + N_2$.
(2) By heating a mixture of ammonium chloride and potassium nitrite:
$KNO_2 + NH_4Cl = KCl + 2H_2O + N_2$.

To distinguish nitrogen from hydrogen: Plunge a lighted taper into a tube of the gas; if the gas is nitrogen, the taper will be immediately extinguished and the gas is not ignited. If the gas is hydrogen it will burn at the mouth of the tube with a pale blue flame.

4. *Lead pipes for water are objectionable* because, after oxidation, the lead is dissolved in the water, and may produce lead poisoning. If the water is very pure, or contains nitrates, or is highly aerated, or contains much carbon dioxide under pressure, it is particularly dangerous; so, too, if the surface of the metal is alternately wetted and dried.

5. *The chemical antidote for mercuric chloride* is a moderate quantity of white of egg. The patient should receive white of egg, or milk, and this should be followed by an emetic, or the stomach should be washed out with albuminous water.

6. *Proteins* are organic, nitrogenous compounds, of very complex constitution, and containing carbon, hydrogen, oxygen, nitrogen, and occasionally sulphur, phosphorus, or some other element. In the human body they are derived from the protein food ingested, and consist of combinations of amino-acids, called polypeptides. The chief proteins are: Albumins, globulins, albuminoids, nucleo-proteins, proteoses, and peptones.

7. *The bile pigments* are: (1) *Bilirubin*, which may occur as an amorphous powder or in crystals; it is insoluble in water, soluble in chloroform and benzine; toward bases it behaves like a phenol, forming soluble salts with the alkali metals. (2) *Biliverdin*, which is amorphous, insoluble in water and in chloroform, but soluble in alcohol.

8.

	COW'S MILK	HUMAN MILK
Reaction.....	Amphoteric	Amphoteric
Specific gravity..	1027 to 1035	1026 to 1036
P'ctage of cream.	3.5 to 4	4 to 4.5

9. *Fermentation test for glucose in urine:*
"Take three test tubes, A, B, and C, place in each some washed yeast; fill A completely with the urine to be tested, and place it in an inverted position, the mouth below the surface of some of the same urine in a flat vessel (the entrance of air being prevented, during the inversion, by closing the opening of the tube with the finger until it has been brought below the surface of the urine). Fill B completely with some urine to which glucose has been added, and C with distilled water, and invert them in the same way as A; B in saccharine urine, and C in distilled water. Leave all three tubes in a place where the temperature is about 25° (77° F.), for twelve hours, and then examine them. If gas have collected in B over the surface of the liquid, and none in A, the urine is free from sugar. If gas have collected in both A and B, and not in C, the urine contains sugar. If no gas have collected in B, the yeast is worthless, and if any gas be found in C the yeast itself contains CO_2. In the last two cases the process must be repeated with a new sample of yeast." —(Witthaus' *Essentials of Chemistry.*)

Trommer's test for sugar in urine: To the suspected urine, in a test-tube, add about one-eighth of a 1:10 solution of sodium hydroxide or potassium hydroxide; then add two or three drops of a 1:10 solution of copper sulphate; shake and boil. If sugar is present, a yellow or red precipitate of cuprous oxide is formed.

10. *Quantitative test for albumin in urine:* "Place 100 c.c. of the clear urine in a beaker of 200 c.c. capacity; if alkaline, acidulate faintly with acetic acid. Heat the beaker over the water-bath, add one or two drops of acetic acid, largely diluted with water, when nearly boiling; continue boiling gently until the diffuse precipitate has collected in lumps. Have ready a small filter whose weight, with that of watch-glasses and clamp has been determined. Collect the coagulated albumin upon the filter, wash with H_2O containing a little HNO_3, then with boiling H_2O until the filtrate no longer forms a precipitate with $AgNO_3$, then with alcohol, and finally with ether. Dry the filter and contents in the air-oven, and weigh between the watch-glasses. The difference between this last weight and the one first determined is the weight of dry albumin in 100 c.c. urine, which, multiplied by 1/100 the quantity in twenty-four hours, gives the elimination of

albumin in twenty-four hours."—(Witthaus' *Urinalysis.*)

PATHOLOGY.

1. CHRONIC ENDOCARDITIS. *Etiology:* "The great majority of cases are the result of an attack of acute endocarditis following rheumatism, chorea, or the infectious diseases. A chronic endocarditis from the onset may be caused by alcoholism, syphilis, gout, or excessive muscular labor. Chronic Bright's disease is also an exciting cause. In elderly people, chronic endocarditis may often be due to atheromatous or fibroid changes."—(Hughes' *Practice of Medicine.*)

Pathological anatomy: "There are two main anatomical varieties of chronic endocarditis, which may occur separately or together: (1) The endocardium is thick and dense, its surfaces are smooth or covered with small, hard vegetations or ridges; it is often infiltrated wtih the salts of lime. (2) There is a growth of connective-tissue cells in the endocardium, with a splitting-up of the basement substance. Some of the new cells continue to live, others degenerate. By the combination of such a cell growth and destruction the endocardium is in some places destroyed, in others changed into projecting vegetations. Fibrin is deposited on the roughened surfaces. After a time the condition may be further complicated by the shrinkage and deposition of the salts of lime in the new tissue and in the endocardium. All these changes may extend to the wall of the heart beneath the endocardium. As the result of the new formation of connective tissue the cusps of the valves may be shortened or grown together or adherent to the heart wall. The chordæ tendineæ may be shortened and the papillary muscle fibres shortened and distorted. The most important result of chronic endocarditis is its effect on the heart valves, producing insufficiency and stenosis. The changes in the valves are followed by changes in the walls and cavities of the heart, and the disturbances of the circulation throughout the body."—(Delafield and Prudden's *Textbook of Pathology.*)

2. The usual lesion of external anthrax is called malignant pustule. It begins as a papule, which is noticed at the point of inoculation; this soon becomes a vesicle and contains a fluid. Around the vesicle is an area of inflammation, which is indurated and edematous. The inflammatory process spreads along the lymphatics, and lymphangitis, lymphadenitis and edema result. The mode of infection is inoculation through a cut or abrasion of the skin. The diagnosis is not difficult; it may be distinguished from carbuncle by the absence of pus and of the core. A bacteriological examination of the fluid for the anthrax bacillus will settle the diagnosis. Death is due to bacteremia.

3. *Etiology of thrombosis:* Injury to the wall of the blood vessel, disease in the vessel wall, particularly the intima, slowing of the circulation, inflammation or degeneration, changes in the blood by which its coagulability is increased, presence of foreign substances in the circulation.

4. STRUCTURE AND EVOLUTION OF THE TUBERCLE.—Grey miliary tubercle is the smallest tubercle visible to the naked eye. It consists of a number of submiliary tubercles or giant-celled systems. Each giant-cell system consists of:

Centrally Placed Giant Cell: Measure 50-500 μ. Many (20-50) nuclei massed near periphery. Bacilli are in the cell opposite to nuclei. Often presents coagulation necrosis (caseation).

Epithelioid Cells: Placed in a zone round giant cells. Each is two to three times as large as a white cell. Elongated, with oval nucleus. Contain tubercle bacilli in or between them. Most characteristic feature of tubercle.

Leucocytes: Form a peripheral zone. Certain no tubercle bacilli. Result from inflammatory reaction round tubercle.

Reticulum: Fibrillar network lying between above cellular elements.

Later stages in the tuberculous process:

Caseation: A number of miliary tubercles join to form a mass formed of all three kinds of cells. Blood vessels being scanty or absent, necrosis takes place. This cell necrosis produces a cheesy structureless mass, known as caseous material. Caseation is best marked near the center of the tubercle.

Cicatrization: This is a proces of repair. The granulation tissue surrounding the caseous center is converted into fibrous tissue, and contracts. The liquid parts of the caseous material are absorbed, and the remainder forms a chalky mass—the so-called calcareous transformation.

Liquefaction or suppuration: This is similar to ordinary suppuration, but it takes place without the usual signs of inflammation. A chronic abscess is formed.

Pyogenic suppuration: In localities, *e.g.* the lung, when free access to the air occurs, or in any lesion where contamination from the skin or alimentary tract has taken place, a true pyogenic infection is set up which rapidly destroys the tissues and produces all the signs of pyogenic absorption.—(From Groves' *Synopsis of Surgery.*)

5. *Paratyphoid fever* "is clinically almost identical with enteric fever. Enlargement of the spleen, rose-spots, diarrhea, and sometimes hemorrhage are its symptoms, and its course is like that of enteric, though it may be briefer. Ulceration may be present, but perforation does not occur, and the mortality is small. It is due to the paratyphoid bacillus, which microscopically resembles the bacillus of Eberth, but differs from it in cultural characters and agglutinating reaction."—(Wheeler and Jack's *Handbook of Medicine.*)

6. In *chlorosis:* "The blood is paler than normal and watery. The specific gravity decreases progressively, and the solid matter is deficient. Increased coagulability is sometimes observed. The number of red corpuscles may be normal even in well developed cases, but the proportion of hemoglobin sinks progressively. In prolonged cases the corpuscles become reduced in number, but the deficiency of hemoglobin continues to be excessive. Severe cases of chlorosis frequently show 3,000,000 or 2,000,000 red corpuscles per cu. mm. and 30 per cent. to 20 per cent. of hemoglobin. The red corpuscles may be little altered in appearance in the early stages; later, irregularities in size and shape are frequent, and nucleated red corpuscles (especially small forms) make their appearance. The latter sometimes occur in great numbers in crops (blood crises). The leucocytes are usually normal in number and kind; but in some cases myelocytes have been met with."—(Stengel's *Pathology.*)

7. *Hobnail liver:* "Early in the disease the organ may be somewhat enlarged, but in the typical stage the liver is small, contracted, the surface irregular, the color varying greatly, is very hard, dense, and cuts with great difficulty. The nodules that project are composed of liver-cells, while the depressed areas are formed by bands of connective tissue that have contracted. These bands are grayish in color, the elevated portions yellowish or brownish, the color depending upon the fatty degeneration or the presence of bile. Microscopically the process begins as a localized infiltration of round cells about the interlobular branches of the portal vein. This is followed by a proliferation of the connective tissue with the formation of new fibers. These increase in number, and undergoing contraction interfere with the circulation. This gives rise to certain associated symptoms, as ascites, gastro-intestinal catarrh, hemorrhoids, and distention of the superficial abdominal veins (the caput medusæ). Jaundice is seldom present. The entire lobule eventually becomes surrounded, and as the contraction continues the hepatic cells undergo atrophy till at last there may be an island composed of a few epithelial elements. The connective tissue does not tend to become intralobular."—(McConnell's *Pathology.*)

8. *Cloudy swelling* is an old term for albuminous degeneration, "which is a type of cell degeneration which is so often associated with infectious diseases and certain phases of inflammation that it is sometimes regarded as a part of the inflammatory process. The cells in this condition are usually swollen and are more opaque than normal, the nucleus being usually somewhat concealed in the granules, when these are numerous."—(Delafield and Prudden's *Textbook of Pathology.*)

9. *Angina pectoris:* "Various theories have been advanced to explain the occurrence of angina. That of *intermittent claudication* is based upon the analogous attacks of pain which sometimes occur in the legs when

their arteries are partially obstructed. In such a case the circulation suffices for rest or restful movement, but prolonged exertion causes cramplike pain and temporary lameness (claudication). Similarly in a heart poorly supplied with blood (ischemic), or in which the driving power is defective, exertion may cause a temporary exhaustion of the muscle. This condition would be favored by increased peripheral tension, which is sometimes permanently present, and sometimes exists during an attack. It may also be produced by chill (contraction of the peripheral arterioles). But in some cases the tension is permanently low, and then we may suppose that a slight increase of work, which would be no obstacle to a healthy heart, is sufficient to cause exhaustion to a damaged one. It is in cases of hindrance to the work of the *left ventricle* that angina occurs.

Other theories are that the pain is a neuralgia of the cardiac nerves, or that it is due to tension of the ventricular walls, induced by acute dilatation. Allbutt considers that it is not truly cardiac, but originates in the first part of the aorta. Mackenzie, adopting generally the claudication theory, compares the pain to that produced by the obstructed evacuation of other hollow viscera (*e.g.* biliary colic), and regards it as a protective reflex."—(Wheeler and Jack's *Handbook of Medicine.*)

10. *Dry gangrene* occurs when death happens in a part which has been previously drained of its fluids. The usual cause is arterial thrombosis supervening on atheroma or calcification of vessels. If the part is quite dry sepsis does not occur, so it shrivels into a black or dark-brown mass. If putrefaction occurs it becomes very offensive.

Moist gangrene occurs when the dead part is full of fluids, and may be either aseptic or septic, generally the latter. If septic, the tissues putrefy and foul-smelling gas is formed.—(*Aids to Surgery.*)

(*To be continued.*)

Miscellany.

Stamping Out Typhus in Esthonia.—From 15,000 to 20,000 soldiers were ill with typhus when the American Red Cross first entered Esthonia, less than a year ago. The delegation comprised 40 American men, but although there were doctors and sanitary workers among the number, there were no trained nurses. This is Lieutenant Lee D. Butler's explanation of the manner in which the Red Cross took charge of the critical situation. They organized their small band as executives and procured Esthonian volunteers as aids.

The soldiers had made up part of the army which General Yudenich had led against Petrograd. There was lack of hospital space for them when they returned to Reval, the capital of Esthonia, and there was lack of disinfectants. The disease was spreading rapidly when the American Red Cross entered. The Red Cross prepared a large disinfected building for the soldiers. This relieved the congestion. They gave every sick man a bath and shave, a treat that few Americans can realize, for some of the soldiers had had no bath for several months. Many of the men had not seen soap for weeks until the American Red Cross received a shipment of it in Esthonia, and distributed it to those in need.

Esthonian women served as nurses and the convalescents did duty as orderlies. Clothing was provided both for the soldiers and their families. Lieutenant Butler said that during the seven months he had spent in Esthonia he distributed cloth from which more than 40,000 garments were made. After months of hard work the spread of typhus was checked.

The food situation was not so critical. Esthonia, situated on the Gulf of Riga, is a farming country. So there was some grain. Fishing, also, is an important industry and helps the country's food supply. Lieutenant Butler returned to America in September, after more than two years abroad. First he was with the army, but after the signing of the Armistice he enlisted with the American Relief Commission, and later transferred his activities to the American Red Cross. He was sent, under Colonel Ryan, into the Baltic states, and spent the last of his time in Esthonia. His explanation of conditions in Esthonia shows that war-suffering Europe still needs American help. The Fourth Annual Membership Roll Call of the American Red Cross will be held November 11-25, this year.

The Medicolegal Institute at Bucharest.—This institution was established as a morgue by the government in 1894, but it has undergone constant and careful development, and now contains spacious class rooms, lecture halls, amphitheater, museum, radiograph department, dissecting rooms, criminology bureau, and a department of photography. Students from the medical college attend classes at the Institute on Thursday and Saturday afternoons of each week. The amphitheater, finished in white tile, has a wide balcony extending around all four sides for the accommodation of students. The museum contains many thousand specimens. The radiograph room has two machines of the latest type. Two dissecting rooms in the basement contain a complete equipment for performing autopsies. The institution handles on an average of 7,500 bodies a year, as compared with 600 before the war. In the majority of instances the bodies brought in are claimed by relatives or friends before the expiration of twelve days, when interment is made at public expense. Facilities are provided for preserving a body by means of refrigeration pending its recognition by relatives or friends. When a body is unidentified and unclaimed after a period of twelve days, a photograph is taken and filed away for the possible enlightenment of those searching for missing friends or relatives.

Friends' Unit Finances Hospital in France.—Ground has recently been broken for the erection of a model maternity hospital at Chalons, France, to cost one million francs. The undertaking is financed by the Friends' Unit of the American Red Cross, partly from funds which are the proceeds of cost sales of supplies to inhabitants of this region and partly from direct gifts. English Quakers are also participating in the work, which is described as a "venture in international friendship." The hospital, designed to take the place of the temporary dispensaries, hospitals, and babies clinics that have sprung up throughout the devastated regions in wooden barracks provided for the purpose by the American Red Cross, will be the most complete and modern institution of its sort in France. Two American and two English nurses will ensure a permanent coordination of the clinical methods of their countries with those of France. About sixty endowed beds will be set aside for the use of the people of Chalons and neighboring villages.

Medical Record

A Weekly Journal of Medicine and Surgery

THE PSYCHOLOGY OF THE OUIJA BOARD.*

BY J. ALLEN GILBERT, PH.D., M.D.,

PORTLAND, ORE.

THE Ouija Board is based upon a thoroughly scientific and defensible principle. The same principle is manifest in many of the phenomena of life that are accepted without question, though explanation of the same is shrouded in the same mystery attributed to the Ouija. Ouija has the advantage of novelty and advertisement. The commercial aspects of the board will be ignored in this paper.

As introductory to the point at issue, let us select two rather fundamental principles: (1) Every act that we perform is preceded by an imaginary picture of the completed action; and (2) every psychic state tends to its duplication in its physical complement. In fact, both are one and inseparable in experience. It is impossible to separate the physical from the psychical. For present discussion the above principles might be appropriately combined into the one statement that any psychic state proceeds automatically or reflexly to its natural physical equivalent, and vice versa.

Take, for example, so simple an act as picking up a pencil from the desk. If the act is analyzed into its fundamental elements it will be found that the first element in the process is an imaginary picture of the hand grasping the pencil, plus the sensations involved in the act. This imaginary picture is then automatically reproduced by the physical organism and the imaginary experience is replaced by the real experience unless there is something to prevent or inhibit the act as such. Those functions which are not under control of the inhibitive centers are purely automatic and can be counted upon with a certainty in proportion to their freedom from disturbing and inhibiting influences. We can find illustrations of this fact in great number. While the normal metabolic processes are largely automatic they are dependent to a marked degree upon the mental attitude of the individual. The stomach, for example, is fooled into secretion even more thoroughly by the concept of food than by the concrete reality of a foreign substance in the stomach, even though that substance be the best of food. The ingested meal handicapped by the inhibitive influences of strong emotion "lies on the stomach like a lump of lead," while the appropriate psychic state will call out the secretions of both mouth and stomach, even in complete absence of food as such.

*Read before the Alumni Association, Medical School, University of Oregon, June 1, 1920.

The inhibitory influences of the emotions upon the gastrointestinal tract are too common to need emphasis. They have found their way into medical nomenclature under the term "nervous dyspepsia." Ancient literature—pre-eminently, the Bible—speaks of "bowels of mercy and compassion." The effect of the emotions upon the intestines was so manifest that the abdomen was looked upon as the seat of the emotions. Every emotion finds its reflection in every metabolic phase of the physical organism. Syncope, diuresis, enuresis, diarrhea, the various forms of shock, et cetera, present themselves as flagrant examples of the principle in question.

The individual who is scared "stiff," or "white as a sheet" is the victim of an inhibitory obliteration of an automatic process. Fright as a stimulus to peristalsis to the point of overcoming the retaining sphincters has won for itself an expression familiar to all and quite common in street-waif parlance but incompatible with polite society, though extremely eloquent so far as expression of the psychophysical principle involved is concerned.

Automatic action, uninfluenced by the higher centers, is always natural and directed strictly to the purpose for which it was intended. We walk naturally so long as we pay no attention to the process, but as soon as a superimposed conscious state is admitted as an element in the process it becomes unnatural and awkward, even to the point of absolute collapse. The very essence of true stage acting consists in living the part so thoroughly psychologically that there is nothing for the physical organism to do but follow automatically. In proportion as self-consciousness is allowed to intrude itself on the program, to that extent do the shaking trouser, the stiffened muscles, the dry mouth and the quivering lip betray the underlying stage fright. The young man who could enjoy the evening party if he could only leave his feet and hands at home has merely reached that stage in development in which the upper and lower neurons have not as yet learned the necessary team work. He has allowed his consciousness to creep into his hands and feet and it is out of place there. Naturally, it is like a fish out of water.

The stiff-legged walk of the youngest member of our family in the presence of strangers became proverbial in the home. All we older brothers had to do was to glance furtively at his feet as he started across the floor and the picture was complete. The whole musculature was thrown out of gear. Physical and psychical confusion was complete with an effervescence of emotion that was amusing in the extreme.

Back of such situations is to be found a principle which has been appropriately called the motor power of an idea. Take, for example, one of the simplest experiments that can be performed in psychology. Let the attempt be made to hold a suspended plumb-bob steadily and accurately over a dot on the floor. Now, while holding the hand steady in a continuous effort to keep the bob directly over the spot, let your imagination depict the plumb-bob first to the left and then to the right of the spot. If you will continue this imaginary picturing of the bob alternately to the left and right, eventually the bob will start swinging in spite of your effort to keep it directly over the spot on the floor. In this simple experiment is to be found the whole principle of the Ouija in its simplest form. Any flash of consciousness, momentary or of minimal intensity though it be, tends to objectify itself in its physical equivalent. A perfect poker face is an impossibility.

Even our dreams manifest the same principle unmistakably. It is in sleep that the subconscious has fullest play. My memory pictures are very vivid of a dream in which I was actively engaged in a foot-ball game. I can see the ball yet as it came at me in my dream. With one lunge I threw myself upon it with the stern reality of the floor as my only reward for my vigorous tackle. The subconscious dream picture had objectified itself in muscle activity until I was bodily out of bed on the floor. Subconscious life, as well as conscious life, has its physical counterpart in proportion to the vividness of the psychic states which act as the correlate of the physical concomitant.

One of our confreres refuses to have an office higher from the ground than the fourth story because of a strong tendency for him to jump when looking out of the window. While standing on the top of Baker Theater with a companion during the passing of a recent parade, I detected him standing with one foot propped against the bottom of the parapet and his head and body leaning somewhat backward. He explained the fact by saying that the advanced protecting foot gave him some feeling of assurance against a tendency to jump which he admitted was very strong in him. Everybody has this tendency in proportion to the intensity of the imaginary picture relative to jumping and for some the situation is not without danger. In such the tendency becomes uncontrollable and occasionally reports of suicide by jumping from a window or precipice creep into our papers, whereas, if the facts were known, in many of these cases we would recognize, not a real suicide, but an automatic transplantation of a subconscious state into its complementary overt act.

This principle invades the realm of conscious life also. We all tend to do the thing that our imagination depicts or that is suggested to us, whether that suggestion be an autosuggestion or one initiated from without. It is often difficult to separate the conscious from the unconscious response to stimuli. Fresh from college and the examination in psychology, a friend suggested that we try out this principle on a farmer who was strolling leisurely down the platform of the depot. In a sharp strident voice, my friend cried out, "Sit down." As though shot, the farmer dropped but caught himself before falling completely. The subconscious reaction was practically instantaneous. In the meantime, consciousness gained time to analyze the situation and he became the very picture of anger that he should have been taken so unawares. His lower neurons had simply stolen a march on him while the upper neurons with their voluntary control were at a minimum, or, at least, belated.

Bed-wetting comes under the same category. The bladder becomes full. The message goes to the cord asking for relief and if the inhibitory centers are off duty, as they are in early life or in sound sleep, the whole process is confined to the lower neuron as a mere reflex and the message goes back releasing the sphincter and evacuating the bladder, shunting, as it were, the collateral activity of the upper neuron. When the upper inhibitive centers are on duty, the inhibition is in proportion to the intensity of the psychic state represented by the upper neuron. When the upper neurons are only sufficiently active to accomplish partial inhibition of the lower neurons, the stimulus from the lower neurons is not entirely lost and the day may yet be saved by the subconscious. The stimulus frequently serves as the framework of a dream which depicts the boy in an appropriate place for evacuation of the bladder. This dream picture naturally tends to objectification, thus reducing the inhibitive powers and the lower neurons are able to break through the weaker inhibition and a wet bed is the result. In the great majority of cases, if not in all, the wetting of the bed is but the objectification of subconscious states as represented in dream life. As the upper and higher inhibitive powers are more and more developed the habit is gradually broken by a more and more complete control of the upper over the lower neurons. However, even in adult life the stimulus from the bladder combined with an extremely vivid dream picture will break down the controlling inhibition and even we adults are embarrassed at times by a partial evacuation of the bladder under the deceptive trickery of a vivid dream. Full consciousness usually intervenes to head off the process before the bladder has emptied itself sufficiently to carry the incriminating evidence over to the next morning. Unless we show the good sense to rise and empty the bladder voluntarily the same program will be repeated.

It requires a process of education to be able to read to onesself without moving the lips in the process because of the universal tendency for psychic states to repeat themselves in their physical equivalents. The man who goes muttering along the sidewalk betrays by every expression the mental attitude he is in. Even the character and speed of his gait reflect the general mental picture that betrays itself in his muttering speech. Such an individual merely follows the line of least resistance which allows every emotion to be translated completely into its physical correlate without obstruction or inhibition. If he will pull himself together, as it were, and analyze the situation he will find that his mental pictures are carrying him through the experience which his lips are depicting to an imaginary audience. Strictly speaking, he is not talking to himself but to the object of his imagination and his imagination is running riot

both in the stimuli that it gives out and the rat-a-tat-tat which he is playing on the physical organism without interference from without.

The crystal gazer entertains himself with the same sort of phantasmagoria. The pictures he sees are but objectifications of his subconscious states in response to the meager stimuli offered by the crystal. He sits gazing listlessly into the crystal with conscious effort reduced to a minimum and immediately in the crystal appears a genuine panoramic objectification of his own subconscious thoughts and imaginary pictures, which he reads off as though they had all the objective reality of the world of things. A bed of red-hot coals in the fireplace will often give better results than the crystal, and many are the individuals who reap extreme pleasure from this form of entertainment as they loll listlessly in front of the open fire.

The description of faces by mediums is probably a duplicate of the same principle.

Not everybody is able to throw himself into that spirit of reverie which is necessary to results in the tapping of the subconscious by various methods such as cited above. Everyone, however, does have a storehouse of subconscious knowledge from which he draws when the proper association appears or when the conscious subsides sufficiently to allow the subconscious to strut upon the stage. No conscious experience is ever forgotten; it is in the subconscious; all it needs is the proper association or the subordination of consciousness to a sufficient degree to allow the subconscious to appear. This is exactly what happens in dreams and trances.

As we advance into the higher types of such phenomena we encounter the automatic writer, the somnambulist, presentiments, so-called "hunches," prophetic dreams, clairvoyance, et cetera, all of which are to be explained on the same basis, viz., displacements of the conscious by the subconscious which has gained temporary control of the physical mechanism common to both.

Those human alarm clocks who are able to set their mental machinery to wake at any set hour of the night, those animated compasses who retain an infallible sense of direction, those vivified barometers who are always able to sense an oncoming storm, and similar enigmata from the standpoint of scientific explanation are but exemplification of an underlying subconscious store of knowledge varying with the individual.

There is a more or less general belief in the instinctive intuition of woman as compared with the more logical conclusions of man. On a snap judgment she is more likely to be right than man. Her only reason for her opinion is the proverbial "because." She has no other but she does have "hunches" and these "hunches" are but the outcroppings of the subconscious which is undoubtedly less under the domination of the conscious in woman than is the case with men. So-called "hunches" are of value. If in doubt on two opinions not subject to logical proof, always take the first—it is more liable to be right. For example, if in writing a letter you write a word and then doubt as to whether you spelled it correctly, the chances are that it is spelled correctly. If you stop to discuss it or consider it at length, you might as well go to the dictionary and look it up. Final decision gets harder and harder unless some logical reasoning offers the solution. Socalled "hunches" or presentiments are not accidents or coincidences by any means. They are outcroppings of the subconscious, and are often of value.

Practically all of us have had experiences such as are detailed in this paper. Comparatively few—possibly none—have had experiences as automatic writers or somnambulists, merely because we are unable to dissociate various groups of experiences and deal with them on a separate basis. Degrees of success with these various phenomena must of necessity vary with the individual.

The somnambulist rises in his sleep, walks about as though awake, performs remarkable feats that are impossible in his waking self and returns to bed with total amnesia for the period of time in question. Mental tasks that were impossible before retiring are now performed with ease and, to his surprise, he finds an hitherto incomplete task finished on his desk, his own handwriting and the testimony of his friends being guarantee for the fact that he himself performed the task. There is but one explanation to be offered. The subconscious has taken the field and, through the agency of the physical organism, has carried out the process, which, so far as self-conscious personality is concerned, represents a true and more or less complete dissociation of personality.

The automatic writer presents a condition of even greater complexity and yet even more to the point in the explanation of Ouija. With his mind absorbed in some book or mental process which engrosses his attention, it will be seen that the hand of the genuine automatic writer is completely anesthetic, grows restless, and makes aimless indefinite motions—a sort of abortive attempt at writing. The hand, in addition to being anesthetic, seems entirely out from under the control of the consciousness. If the hand is now screened from his view, the aimless movements become somewhat more definite. If a pencil is put in the hand, it will begin to move and write with an aimless scrawl or semblance of writing. Ask the hand a question and it will write off hastily an answer to your question. Extended conversations can thus be called out from the anesthetic hand. After the sitting is over, the subject is completely unaware of having written anything and denies authorship of the things written.

It is exactly as though some highly musical member of the family has temporarily deserted the piano, giving an opportunity for one of the younger and less skilled members of the household to mount the stool and inflict upon us his special improviso strains which are a peculiar mixture of discords with just sufficient chords to remind you that it is music.

In such facts as these we are face to face with the principle underlying Ouija. Automatic writing, planchette, and ouija are all based upon the same principle. They are all forms of automatic writing in which the subconscious uses the mechanism at its disposal to strut upon the stage and delineate facts which are otherwise crowded out of full conscious life. No one is more surprised at the results than the individual who is operating the board. Not understanding himself, he naturally

attributes it all to external agencies. To be sure, there are all grades of fakes but there are also true automatic writers who can successfully use this means of tapping the subconscious. If not understood, there is little wonder that the phenomena are attributed to spirit control, messages from the dead, or communications of the supernatural. The true writer swears he is not manipulating the ouija board. His statement is only partially true. He is not moving it consciously but is certainly moving it subconsciously. He is as unconscious of the process as is the man who goes to bed and is unconscious of the dissociated personality that rises in the somnambulistic perambulation and does all sorts of feats without conscious recognition of the experiences when in his normal waking self. After a sitting with the automatic writer he does not identify himself with the writing performed by the anesthetic hand. The only way that ouija differs from this process is in the fact that ouija *spells* out while the automatic writer *writes* out the dictations of the subconscious.

Not every man can manipulate ouija. For some it does nothing. For others, merely to touch it and ask it a question will insure prompt answer to the same. It varies with the individual. The highest success in the manipulation of ouija requires two main elements in the individual: (1) The power to dissociate various groups of experiences; and (2) a marked tendency for psychic states to go over automatically into their physical correlate. Variations in these elements furnish the multitudinous degrees of success to be found in various individuals. Where both of these elements are present to their maximum intensity in the same individual. the ouija furnishes a valuable method of tapping the subconscious. Ouija does not move of its own accord nor is it moved by powers outside the individual manipulating the same. The answers you get from ouija are but the embodiment of subconscious states, significant or insignificant in proportion to the intimacy of the relation that can be established between conscious and subconscious states.

SELLING BUILDING.

THE PATHOGENESIS OF DEMENTIA PRÆCOX.

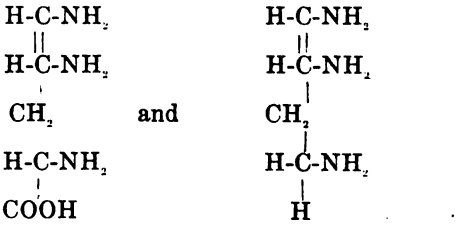
BY BAYARD HOLMES, M.D.,

CHICAGO, ILL.

THAT dementia præcox is always associated with profound anatomical and histopathological lesions has been clearly demonstrated by a large number of authors. The paper by Renaudíe[1] is an admirable summary of these findings. C. V. Monokow and S. Kitabayashi[2] have more recently shown that the choroid plexus is uniformly involved, inflamed and atrophied in dementia præcox. These authors conclude in both instances that dementia præcox belongs to the class of autotoxemias. This is a view that the author has defended repeatedly in the past, and supported with clinical and laboratory evidence.

The clue to the possible source of the toxins was first obtained from the observation that dementia præcox patients always suffer from obstinate chronic obstipation. The patients are constipated in a peculiar way, because the ring of Cannon, which is normally inoperative in man, is so markedly constricted in these patients that a barium meal, although it traverses the entire length of the small intestine in the normal time interval of less than six hours, frequently remains in the cecum for five days, and parts of it have occasionally been found there at the end of three weeks and more.[3] Such part of the food as has escaped absorption in the small intestine, because of its long retention in the cecum, will be far more liable to a destructive putrefaction than is normally the case. The products of such a putrefaction are many and variable, depending apparently upon the variety of (1) organism present, (2) the nutritive conditions, (3) the temperature, (4) the hydrogen ion concentration of the medium. Of these products, the amines produced by the decarboxylation of the amino acids seem to be the most toxic. These amines can be grossly divided into two varieties, the monamines, such as amylamine and tyramine, and the diamines, such as putrescine, cadaverine, and distamine. The monamines raise the blood pressure and are, so far as we know, less toxic than the diamines. The diamines lower the blood pressure, and histamine, the diamine derived from histidine by decarboxylation, is by far the most toxic of the known diamines.[4]

A third group of amines, that one might possibly call triamines, has recently been suggested by Koessler and Hanke[5] as possible products of bacterial metabolism. These compounds, also derivatives of histidine, are represented by the following formulæ:



Judging from the formulæ, one would predict that these triamines should resemble histamine physiologically. Unfortunately there is not only no literature concerning the physiological properties of these compounds, but the compounds themselves seem not to have been prepared. They are particularly interesting because although they contain the active part of the imidazole ring, the ring itself is absent; so the compounds would give no characteristic color reactions. They might, therefore, be easily overlooked.

The organism that is most abundant in the alimentary tract is *B. coli communis*. That certain strains of this organism are potent under proper conditions, in producing histamine from histidine, has been proven by the work of Mellanby and Twort[6] and by that of Koesler and Hanke.[4] In order to substantiate the claim that dementia præcox is a toxemia caused by the absorption of toxins from the alimentary tract, it is, therefore, no longer necessary to search in the stools for the *B. aminophilus intestinalis*, of Bertholet and Bertrand.[7] It would be far more instructive to inoculate a synthetic medium, such as was employed by Koessler and Hanke, with a sample of feces from a dementia præcox patient and analyze the resulting liquid according to the demonstrated and advised

scheme by those authors.[8] If this mixture of organisms were invariably capable of producing histamine, this would certainly be a strong substantiation of the theory of a toxemic condition. If histamine were absent, however, other toxic substances, possibly the triamines above mentioned, might be present as the result of putrefaction, and their presence could be established biologically.

Some time ago Julius Retinger[9] was able to show that the stools of dementia præcox patients contained depressor substances that behaved like histamine, and that normal stools were generally free from such substances. Now that a much more delicate and reliable chemical method for estimating histamine has been worked out,[8] these experiments should be repeated to see if the depressor substance in the stools is histamine or not.

For some years I have held and expressed[9] the view that dementia præcox is caused by toxins that are produced by the action of bacteria in the intestinal tract. Although similar toxins may be produced in the normal individual, their amount must be much smaller because the rapidity with which the intestinal contents are dehydrated in the cecum and discharged into the colon in a solid condition. The dementia præcox patient has a spasmodically occluded colon which permits the process of decay to be very far-reaching. Under these conditions large quantities of toxic substances are absorbed by the active cecal wall, and carried into the blood and to the liver. This master detoxicator destroys the toxins as long as their concentration is not too great. The time comes, however, when the poisons pass beyond the liver into the general circulation, where they produce a selective gradual but deadly degeneration which includes the cerebral tissue and possibly the choroid plexus.

The above view is substantiated by the following facts: (1) The blood pressure in dementia præcox patients is always low, and an injection of adrenalin, instead of producing a marked rise as is the case in normal individuals, usually causes the blood pressure to drop still lower. The peculiar behavior of persons to whom ergot has been administered is certainly suggestive in this connection. Ergot contains histamine.[10] Its administration produces a marked fall in blood pressure, which cannot be elevated by a subsequent injection of adrenalin. (2) The extremities of dementia præcox patients are often cyanosed, edematous, and cold, and occasionally ecchymotic and necrotic. The veins of the lids and abdominal wall are also greatly enlarged. Here too there is a marked resemblance to ergotism.[11] (3) Excessive salivation is frequently one of the distressing symptoms of dementia præcox. Histamine is a powerful salivary stimulant. (4) An acute onset of dementia præcox is associated with an acetone breath, an aromatic perspiration and a urine smelling of orange blossoms. These are the characteristics of an acidosis. Under these conditions one would expect the intestinal contents to have a high hydrogen ion concentration which is favorable to the production of histamine from the histidine by the colon bacillus.

It might not be out of place to remark here that some of the distressing symptoms of any acidosis may possibly be caused by amines. It is a well established fact that the excretion of ammonia is very markedly increased in cases of acidosis. The ammonia is formed from the amino acids by a process of deamination. In order that this ammonia may be of service as a neutralizer of acidity, the remainder of the amino acid molecule, with its attached carboxyl group, must be oxidized to carbon dioxide. Although this is undoubtedly the normal process, an occasion might arise where the amount of acid produced would be so excessive that this normal process of neutralization would be inadequate. Under these conditions *the normal body cells might decarboxylate the amino acids which would give rise, in one step, to a stronger base than ammonia.* The amines generated in this way would then produce a toxemia.

Although the above four parallel cases show that dementia præcox is associated with a set of symptoms that closely resemble a histamine intoxication, there are still several things to consider before one could definitely conclude that histamine, or a pharmacologically similar substance was the determining factor in the symptom complex known as dementia præcox: (1) Has histamine, or a substance containing this amine, ever been known to produce insanity? (2) Will the continued ingestion of histamine produce an athropy of the nervous tissue and of the other organs resembling those pathologic conditions found in dementia præcox? (3) Do dementia præcox patients improve when steps are taken to prevent the far reaching intestinal putrefaction with which this disease is so constantly associated?

Has Histamine or a Substance Containing This Amine Every Been Known to Produce Insanity?—Histamine in pure form has never been ingested by man in sufficient quantities nor for a sufficient period of time to make any definite statement as to its effect; but ergot, whose most potent constituent is histamine, has been the cause of considerable intoxication throughout Europe and especially in Russia. It is known and described as epidemic ergotism. G. A. Kolassow, in his review of the Russian literature on ergotism, has shown that 27 per cent of all cases of ergot poisoning *have shown some deteriorativ phycoses that are very similar to dementia præcox,* and that these conditions occur almost exclusively in the adolescent, leaving them if they outlive the other symptoms of the disease in a permanently subnormal mental condition, if not permanently insane or demented.

Will the Continued Ingestion of Histamine Produce an Inflammation and an Atropy of the Cerebral and Nervous Tissue and the Tissues of Other Organs Resembling Those Characteristic of Dementia Præcox?—Unfortunately no researches have been made in Europe or America which answer this question. Until the late publication of Koessler and Hanke, no method of producing histomine in such quantities and of such purity as the problem requires was available. Histamine is now on the market. The problem is fairly well set out. The cerebral, the choroidal, the retinal and the gonoidal lesions are specifically recognized and described, and can be collated through the writings of Southard, Alzheimer, Ranaudíe, Blin, Todd, and Carlo Cini. The problem is a *major opus* of the most intense practical, social, theraneutic and economic interest, and deserving the effort of the

reddest-blooded scientists and the support of the most hard headed directors and trustees of research funds.

The meager knowledge that is now at hand relative to the action of pure histamine, leads the writer to predict that no permanent cellular lesions will be produced by uncombined and pure hastamine. The fatal issues of histamine intoxication are so abrupt that celular destruction and degeneration have not had time to appear. However, the absence of all histopathology in these animals has always been confusing and has aroused doubtful speculation.

The case with combined histamine is yet undetermined. The composition of these substances is still problematical and conjectural, though they are readily recognized and quantitatively estimated by the Koessler-Hanke method. Some instances of intoxication with imidazol-containing material (ergot for example) shows cellular and other histologic pathology which resembles the cerebral lesions of dementia præcox. This has been observed also in rare instances where uncertain biologically produced histamine has been injected into an animal without producing the expected sudden death.

So though this *opus* is so well laid out, the pure histamine provided, the delicate quantitative color test established and a large amount of chemical biological and serologic detail furnished, the evidence at hand requires the extension of the research to the imidazol-containing products of the growths of intestinal bacteria of every strain found in the human cecum.

Very much study and research has already been put upon the *B. coli communis,* but not enough to furnish the equipment and requirements for this investigation. It is just enough to show the most astounding differences in the conditions of life and rapidity of multiplication of various stirps of the *coli* and an equally astounding difference in the products of growth of different strains, even under identical conditions and on an identical medium.

We must wait the answer to this question, and to the auxiliary questions which this question in its simplest form naturally involves, with hopeful expectancy. But in the meantime there are great possibilities of therapeutic use of the presumptions our meagre and fragmentary knowledge suggests.

While no evidence exists that histamine produces the cellular lesions in experimental animals comparable to those found in dementia præcox, there is evidence that combined histamine (ergot) does produce cellular lesions and symptoms resembling those of this disease.

Do Dementia Præcox Patients Recover or Improve When Steps are Taken to Prevent the Cecal and Colonic Putrefication With Which This Disease is so Constantly Associated —This is asking for a clinical experiment. It is not now a fashionable form of research, but it is one which appeals very strongly to the friends of the patient, and is not to be despised. In other articles especially in the reports published in Dementia Præcox Studies during 1918 and 1919 of the patients examined in my laboratory, it will be noticed that I tried three distinct methods of detoxicating dementia præcox patients.

In one group of cases the procedure used on alcoholic, morphine and cocaine habitués, known as the Towne-Lambert Treatment, was tried out. The remedies were very kindly and generously furnished by Mr. Towne himself. While my staff of assistants did their best they were inexperienced in the use of the remedies and hardly dared to carry out the daring experiment. Anyway, the results were negative.

Somewhat more successful was the detoxication by the intravenous injection of large quantities of normal salt solution. (v. Dementia Præcox Studies, 1, 1919, pp. 49-60m, 61-66, 105-110, and 2, 1919, pp, 147-149). However, most of my patients were unmoved by repeated and frequent intraveneous injection of large quantities of sterile isotonic solutions. Incidentally I wish to remark that large intraveneous injections of a highly saturated solution of glucose was also tried out without one case of betterment.

On the same group of patients the fear of a neutritional toxemia lead to the use of "vitamine." Dr. Julius Retinger prepared from rice polishings a considerable quantity of the alcoholic extract, but it was wholly ineffective with dementia præcox, though it cured two Chinamen of beriberi in a most miraculous manner, thus showing its proper preparation and its potency.

It was after these experiments were made that the cecal stasis was attacked by appendicostomy. The barium meal had demonstrated a cecal retardation in front of the ring of Cannon, extending beyond the fifty-four hour séance sometimes extending even into weeks. Therefore appendecostomy was undertaken. This was done only after the inefficiency of enemas to reach beyond the ring of Cannon had been demonstrated in each case.

There was much to learn in making an efficient and permanent appendicostomy, which could not be acquired from the literature of the subject. Greater or less pathology was found in the cecal region of nearly every patient. In some there was a greatly enlarged appendix and in others the lumen of the appendix was almost obliterated. In some patients the appendix was retrocecal, or otherwise held back from the abdominal wall, and in one case the appendix had been surgically removed and extensive peritonitis had completely buried the cecum, so that the operator mistook a loop or transverse colon for the *caput caeci.* The organization of service at the Cook County Hospital, where many of these operations were performed, put the patients into the hands of different surgeons just as the assignments were made by rotation in the booking office. The number of patients treated is still too small to furnish a quantitative report. There is no doubt, however, that appendicostomy and prolonged daily irrigation of the cecum, with ten quarts or more of warm (100° F.) sweetened water, five hours after the last meal of the day results in physical and mental betterment (v. Dementia Præcox Studies, 1, 1919, pp. 28-29, pp. 129-148, pp. 202-212, pp. 260-267, and 11. pp. (89-95, pp. 173-177, pp. 180-184, pp. 252-256).

There is but one thing to be expected of cecal irrigation through appendecostomy, and that is the arrest of the putrefication in the cecal contents. If toxines produced in the cecum have already destroyed cellular elements and glandular elements

of the choroid and other endocrines, the arrest of the production of these toxins will not restore lost tissues. All that can be reasonably expected is the arrest of the destructive process and opportunity for repair and restoration of function, *i. e.*, re-education and rehabilitation.

Nothing is more convincing than this clinical demonstration of the efficiency of this method in arresting the progress of the disease, yet no other means of restoring the patient should be neglected. Even if the source of the intoxication should be found in the tissues of the body and not in the direct action of the bacteria in the cecum, the value of irrigation can not be gainsaid. If, however, the source of the toxin is ultimately found to be in the cecum, some simpler method which can be earlier and more generally applied is likely to be discovered. Such a remedy was found for amebiosis after appendicostomy had proved valuable in that disease.

The great and the most absolute indication in dementia præcox is massive scientific research on a scale commensurate with the annual loss of young manhood (20,000 a year in the United States) and the expense of the pessimistic custody of our 160,000 patients in the State Hospitals.

AN EPIDEMIC OF KAFFIRPOX IN JAMAICA.

RANDOM NOTES OF A TOURIST.

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

In a recent tour of the tropics, the writer happened to be at Jamaica during an outbreak of a disease similar to smallpox, but differing from it in many ways. Various names have been given to this strange affection, such as epidemic varioloid-varicella, alastrim, West Indian modified smallpox, and Kaffir milkpox.

The question has been raised as to whether the disease is chickenpox or smallpox or some modification of either of these diseases. The following history of a patient that I saw several times through the courtesy of Dr. McLean of the United Fruit Co. shows most of the features of an average case.

Joseph D. Twenty years. White. Has always lived at Kingston. Had an attack of typhoid fever when three years old. Since then he suffered from recurrent attacks of malaria until he was fifteen years old. He was then sent to the mountains for a prolonged stay and has since had no manifestation of this trouble. In 1918 he had a mild attack of influenza. On August 7, he woke up feeling chilly, with a mild headache and aching in his bones. He thinks he had fever but the temperature was not taken. On August 8, he stayed in bed and took quinine. He could not eat but drank much ice water. On August 9 he sent for the doctor. He was vomiting, felt weak, and was found to have a temperature of 103°. On August 10, spots began to appear. The vomiting stopped and the temperature fell to normal. On August 11, there were spots on his face, arms, and whole body, including the palms of the hands and soles of the feet. He describes them as red spots that gradually "came to a head." On August 17 and 18 the pocks had completely formed. He states that on rubbing the skin pus could be seen. He complained of pain in the palms of the hands and soles of the feet, evidently due to tension of skin. Otherwise he felt perfectly well with a good appetite and slept peacefully for the first time since his illness. On September 4, an examination of the skin showed a staining of the spots over his whole body. They exhibited a deep bluish-purple discoloration. No pitting.

Two weeks ago his father was attacked with the disease which has run about the same course but in a slightly milder form.

Dr. Langeley Hunt, Senior Medical Officer of the Island, kindly gave me the following data of the epidemic:—Last November chickenpox appeared on the Island and soon many were attacked. As this disease was not then reportable the extent of the epidemic was not definitely known. On May 7, a supposed case of smallpox was reported, but investigation showed that the disease was not smallpox. It was evidently a case of Kaffirpox as since that date this disease has been spreading over the Island and is now epidemic. Both chickenpox and Kaffirpox are now reportable diseases on the Island.

On Aug. 30, with the kind permission of Dr. Hunt, I made a visit to Bumper Hall. This is a pest house in the suburbs of Kingston, which consists of a number of separate buildings in an area of several acres surrounded by a stockade to insure the quarantine. Over three hundred patients were isolated here at this time. The cases that I saw differed clinically from both chickenpox and smallpox although showing some features common to both diseases. The pocks were especially abundant on the face and also scattered over the wrists, arms, body, and legs. In all the cases examined, the palms of the hands and soles of the feet were covered with pocks. I have never seen this condition in chickenpox though it is common in smallpox. One man who was covered with pocks had been vaccinated after the eruption had begun and this vaccination was successful; this would not have occurred if the original disease had really been smallpox. Many complained of sore throat and pocks were seen in a number of throats that were examined. Most all of the cases were followed by more or less superficial pitting in the face. This was evidently due to the natural course of the disease and not to accidental or secondary infection such as is occasionally seen in chickenpox. The pustules were unilocular in the cases examined and apparently did not extend very deeply into the true skin. There did not appear to be a true umbilication, though some pocks showed a slight retraction in the center apparently due to a drying of the pustules. The pocks were fairly uniform in age thus differing from the papules and vesicles of chickenpox. A deep

purple staining of the skin persists for several weeks after the drying of the pocks. The nurse in charge stated that the patients were only really sick at the beginning of the disease, when malaise, headache, and backache were more or less marked. The fever as a rule was not high, running from 101° to 102°, although a few cases did have a much higher temperature at this time. When the pocks began to appear, the temperature usually dropped to normal and the patients felt well. As a rule there was no secondary rise in temperature when the pustules began to form. Indeed most of the patients developed a very hearty appetite at this time and were continually asking for food. It was amusing to see many patients, with face and body covered with pustules, walking about the grounds, half clad and smoking cigarettes as if nothing were the matter, although they had every appearance of ordinary smallpox. Many complained of pains in the feet, apparently due to the stretching of the skin by the pustules. There were no sequellæ. Up to this time there were only three deaths, one in a marasmic baby, one occurring from an abortion in a delicate woman, and one from hemorrhage. It was thought that in these cases the fatal issue was not directly due to Kaffirpox. Infants and young children are attacked but usually have the disease in a very mild form.

Dr. Moody, the bacteriologist of the Island, is making a careful study of the epidemic and will later render a complete report of his observations. He kindly gave me some of the data he had already noted. The period of incubation appears to average from ten to twelve days. The constitutional symptoms, consisting of malaise, headache, slight backache, and fever, continue about three days before the rash appears. The eruption follows the distribution usually seen in smallpox, beginning in the face and then appearing on the wrist, arms, body, and legs. When the rash appears, the temperature drops to normal. The pocks mature by the sixth or seventh day and there is no true umbilication. Dr. Moody has found the deeper layer of the skin involved in several sections microscopically examined, and in one he showed me, the corium was distinctly infiltrated. There is some pain from tension when the pustules mature. In some cases, the mucous membrane of the palate and buccal surfaces is involved. There is very seldom any secondary fever when pus begins to form. In a few charts examined, however, there was a slight upward curve.

Kaffirpox, as now seen at Jamaica, is a very rare disease as may be noted from the few descriptions of it found in medical literature. The only work on tropical medicine to which I have had access is Castellani and Chalmers' volume.* These authors state that one of the earliest descriptions of an epidemic is given by Anderson in 1865 in Jamaica. Dr. Hunt stated that in the Spring of 1903 some cases occurred near Falmouth on the Island.

Castellani and Chalmers give the following points in differential diagnosis:—Kaffirpox differs from chickenpox because of (1) confluence of vesicles in certain cases; (2) Its frequency among adults; (3) The partial protection by Jenner's vaccine. It differs from smallpox by (1) Its low mortality (1 or 2 per cent.); (2) Less severe in children than in adults and often found among babies in whom the vesicles are very small; (3) No secondary fever in children; (4) Though vaccination is in some degree protective, the disease can occur after recent successful vaccination; (5) Vaccination can be successfully carried out shortly after an attack of alastrim; (6) Some believe that an attack of smallpox gives a lasting immunity to alastrim. These authors consider that the cause of Kaffirpox is the same as in ordinary smallpox since vaccination seems to offer protection. An extensive campaign for vaccination is now being carried out by the health officers of Jamaica.

*Manual of Tropical Medicine, Castellani and Chalmers. 3rd Edition, Wm. Wood & Co., New York, 1920.

The disease is quite infectious as shown by the rapidity of its spread. It affects negroes principally; very few whites have been attacked. It is supposed that a passenger suffering with Kaffirpox landed at Kingston from Cuba and thus started the present epidemic. Whether this is true or not, there are many evidences that Kingston and its environs are not in good sanitary condition. A brilliant example of what sanitation can accomplish in the tropics, as shown by little sickness and a very low death rate, is seen in the Canal Zone. Other tropical countries would do well to follow the lead and example of this locality. The present epidemic, though practically without fatalities, cannot but have an unfortunate, although temporary effect on this beautiful Island. One immediate result has been the cancellation of the proposed visit of the Prince of Wales. As the colony is loyal to the Crown and was making great preparations to celebrate this occasion, much disappointment has resulted.

I am indebted to Dr. William E. Deeks, Chief of Staff, and the medical officers of the United Fruit Company for many interesting views of sanitary and health conditions in the tropics. They are doing much to improve sanitary and social conditions in the regions they can control.

51 West Fifty-first Street.

COMMON MOTOR DISORDERS, DISUSE CRIPPLINGS, NEUROSES, POST-INFECTIVE AND OTHERS.

TREATMENT BY MUSCLE REEDUCATION (KINESITHERAPY), MANIPULATION, ADAPTATION, MOBILIZATION, AND PASSIVE-ACTIVE MOVEMENTS (ORTHOKINETICS).

By J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF PHYSICAL THERAPEUTICS AND DIETETICS, MEDICAL DEPARTMENT, TEMPLE UNIVERSITY.

Motor neuroses of many different kinds and degrees follow minor injuries, traumata, and also a wide variety of diseases, infectious and metabolic. The elements of slight traumata and disease process are often combined. Among the phenomena needing relief are rigidities, contractures, tremors, tonic protective spasms, also enervations, pareses, deformations, down to ataxia or mere impairments of motor precision. Of equal significances are lapses from, or retardations of conscious control. Treatment to be effective should be directed not

alone to the primary, the underlying causes, but also to their effects direct and collateral, and in such a way as only to not repair, but to contribute to the cure of disordered energy distributors, subcenters, and local transformers. As an obdurate background, a source of endless obstruction, is the varying shades and degrees of psychopathy and disorders of volition.

The primary disorders or causes are, in most instances, not amenable to radical cure or even to satisfactory repair. The peripheral impairments or disabilities are, however, always capable of amendment, sometimes of clinical cure. Loss of motor control may rarely be complete and yet not be permanent; also these vary as to capabilities of betterment or again exhibit unexpected restorabilities. The key to success is prompt and consistent attention from the earliest, especially during the acute stages. Unless joints, synchondroses, arthroses, or amphiarthroses have become absolutely fixed something worth-while can be done.

The neuromuscular mechanisms will usually be found so sadly disarranged, shocked, jolted, or injured, as to induce varying degrees of permanent disability. Where there has been only such damage to the central or controlling mechanisms as leaves normality in some essential neurons, cells, or structures, these may as a rule be awakened, set in order, adjusted, restituted, and useful control reestablished.

The measures most promising are those directed to the crippled parts, manipulative and mechanical stimulations (orthokinetic) capable of eliciting desired reactions. The means invariably needed are some of the diverse modalities of motion, kinetogenesis, hence we may use the term orthokinetic remediation.

The problem is twofold: (1) to repair the peripheral mechanisms, putting them in condition to function. Then, and not till then, can it be determined: (2) how far the centers are capable of restoration. This can often be obtained even when galvanic responses are negative. Later under improved general conditions they may show unexpected vitality. Wherever there is the slightest capability of voluntary movement, that must be conserved, skillfully directed, and encouraged at all hazards. This is true in acute as well as subacute or chronic conditions.

Physicians, so it seems to me, too often fail to take into full consideration the absolute interdependency between body and mind, constituting as they do one individual unity, whereas psychologists reckon upon this basis uniformly. "Physical training is mental training," is the attention-seizing title of a recent paper by Dr. James McBride (*Scientific Monthly*, October 15, 1915). The immediate applicability of this sound dictum is that in spite of such disablements as even a reaction of degeneration following trauma, one is often surprised by almost unbelievable restorability.

The central object of reconstructive (orthokinetic) motor training is volitional training, a series of exact, purposive movements or procedures from initial impulse to complete coordinated and applied acts.

Heretofore the individual in all probability was never conscious of directing his movements, except by the vague matter-of-factness of acquired automatisms. Now, however, whether full success or failure follows, whatever restoration of coordinative capabilities or semi-helplessness ensues, depends on how completely he can be made to realize the paramount importance of achieving conscious control. A personal confession may help. Although myself vividly interested in this subject, and giving constant attention to clinical problems where motor integrities are aimed at, it is only of late that I have learned to appreciate the infinite complexities, or rather the limitless possibilities and resources of, functional reeducation.

Lameness in arm or leg, in back or neck, frequently persists for the sole reason the sufferer was not intelligently trained in childhood; or, it may be, lacked willingness to cooperate, or most often was lacking in motor intelligence.

Let me pause to emphasize this last point: some men are so clumsy they can only perform those simple acts which absolute necessity forces upon them. In earlier years, while the plasticity of brain and muscle adjustments was at its best, these persons acquired a working set of automatics. This motor capacity in some ceased to be up to par or they suffered from deficiencies in educability, adaptability, variability, and they became motorially (kinesthetically) retarded in mind.

Individuals differ notably in departments and degrees of intelligence, if we admit that motivation is an essential part of intelligence.

Disuse Cripplings Following Injuries, Wounds, and Enforced Inactivities.—In civilian and industrial practice diverse disuse cripplings are met and often persist long after they should have been remedied. The circumstances and findings are not markedly unlike those produced by war. War injuries are kept under control of military surgeons. A certain proportion however, soon or late may require the collaboration of civilian experts. It is well for all physicians to familiarize themselves with the facts, especially diagnostic findings, through tactile apperception and the resources of orthokinetics.

A considerable number of disuse cripplings arise in the exigencies of industrial hurry, pressure, neglect, and the crowding demands of dangerous occupations. The element of secondary or delayed shock must be reckoned with. "Shell shock" is a subject for a civilian to understand as well as the military surgeon. The analogies of phenomena due to bewilderment, "commotio cerebri," are frequently met. They extend to every nook and corner of the body.

In every day experience the primary condition of a patient when injured varies widely and from causes due to mere feebleness or to serious degenerative conditions all the way from youth to late age, from the timid to the courageous, the fidgety, or the apathetic. Hence vagaries, structural and mental vitiations, and vulnerabilities must differ widely. Military men, on the contrary, constitute a selected group of young, sound, vigorous, trained individuals in whom original defects are rare. Hence the element of primary defects is less in evidence.

Motor integrities occupy our immediate attention. One problem is, first and last, to restore

kinesogenic (muscle sense) functions in order to expedite recovery of motor facilities. The outstanding feature of severe injuries, especially of those which are extensive as well as intensive, is a wide-spread perturbation of reflexes, the unit of structure and of defense mechanisms, bearing hurtfully upon centers and subcenters. These gross reflex mechanisms come to be thrown out of gear. Until solved and equilibrated they may cause a bewildering array of morbid phenomena. Localized reflex disturbances deserve patient scrutiny and adjustment.* Both sensory and motor, also static effects are produced, often so obscure as to remain undetected by many competent clinicians.

In wounds, serious or disabling, the question of the gross reflexes becomes commingled with that of automatisms. The partly voluntary, the unconscious, and the controllable reflexes are involved—"gradations of reactions to stimuli which are alike in being native to the individual, but which vary in their relations to states of consciousness, those which are innate and those which are acquired," and all which are subject to jolts, to shocks, and bewilderments. Functional paralyses, rather pareses, due to protracted motor inactivity are common in both civilian and military experience.

Among the possible causes of motor impairments occurring in the absence of any apparent organic nervous lesions, such factors can be reckoned as disorders of reflex action, sympathetic disturbances, suggestibility, emotionality (hysteria), and perhaps unclear changes in the central nervous system and especially the variants in hypo- and hyper-function of the ductless glands.

Prolonged inactivity of a limb or limb segment or group of muscles, acts as an efficient cause of functional paresis. Usually this occurs when a limb has been immobilized unduly long because of a wound, inflammatory process, fracture, or even of mere pain. The joints are then found stiff, the muscles torpid, and all the tissues hypersensitive. In timid, lazy, aboulic, or obsessed individuals, the required personal efforts at mobilization are not made, and to the initial disturbance a paresis is thus superadded through inactivity. Peripherally such conditions occur as muscular atrophy with subnormal irritability to electric stimulation; also decalcification of the bones, joint stiffness, hypothermia, cyanosis, hyperidrosis, and hyperesthesia become established. Where the limb is habitually held in a faulty position, permanent loss of dynamic equilibrium between opposing sets of muscles follows, joint vitality and movements become correspondingly restricted.

Later the nerves supplying the inactive muscles lose conductivity; the spinal motor centers become weakened and depleted of energy, thus increasing the tendency to muscular atrophy. The cortical kinesthetic centers themselves become torpid; kinesthesia and voluntary motion become impaired and the affected limb practically passes from the consciousness of the patient, who carries the helpless part around like a foreign body. A critical period arises in such cases at which the kind of management (discipline) the patient receives governs the ultimate result. At this stage prompt and energetic treatment, if reinforced by wise disciplinary measures, will usually be needed if morbid trends and disabling after consequences are to be avoided.

Atrophies take place in cells leading all the way back to centers, cortical cornual, and spinal, and the subcenters in the ganglia. Likewise compression of nerve terminals and larger trunks is met. Sensory areas, it should be remembered, exist in muscles, fibrous junctures, and joints.

Fibrous structures and junctions of fibrous structures and muscles produce a large proportion of minor distresses and lameness. Disabilities and interferences with voluntary motion have to do also with impaired volition. Volitional training is the outstanding demand from the outset, as has been demonstrated by Willems in acute joint lesions, the surgeons at La Panne in stumps, and others during the late war.

An actual paresis may exist, some part of which is due to disuse and some part to loss of motor response, which may not be permanent. Nerves may have been cut, or parts of nerves or subsidiary nerves or fibers severed or crushed. These may recover or may remain incompetent, in proportion to the promptness and completeness of Volitional training.

Nerves supplying muscles, when rendered inactive, may have lost their conductivity, hence the spinal motor centers become weakened, anemic or atrophied. One word as to treatment, later offered more at length. The physician would be wise to familiarize himself with the special craftsmanship of manutherapy, mobilizations, manipulative orthopedia (orthokinetic). This he should apply himself. If, however, he is disinclined to do so, he owes it to himself as well as the patient to achieve a competent knowledge of the subject in order to direct the masseur who must be taught judicious, scientific muscle reeducation.

Contractures and Paralyses of Reflex Origin and Their Treatment by Simple Orthokinetic or Orthopedic Measures, "Manipulative Surgery," Readjustment, and Nerve Pressure.—A certain proportion of contractures and paralyses are psychogenetic (a psychoneurosis or a psychopathy); a smaller number are due to disease in the central nervous system, the biochemical-metabolic realm; others arise from reflex irritation. Mental perturbations may accompany any or all causes, may aggravate them, may mask them, but when removed by restoring conscious control through suggestion, explanation, reassurance, and volitional (movement) training, they may be reduced in their disabling effects and a practical cure result.

Exact diagnosis is oftentimes difficult enough, even for the most astute and experienced. Differentiation is materially aided by eliminating the mental element and separately appraising the physical residua. Also treatment by the simple means to be described may, and often does, reduce the problem yet further. When after a series of such efforts they continue, then and only then, need we

*We are coming to recognize more clearly the rôle of reflex perturbations as the key to obscure clinical phenomena. Enthusiasts like Albert Abrams first invite scorn of those who omit to examine into the subject, they are called "men of one idea;" later their testimony is welcomed. Attention to the reflex phenomena in explaining states of tuberculosis is directed by F. M. Pottenger. The reflex arc in its motor and sensory spheres is coming to be appreciated, especially in a patient over-stimulated, irritated, or shocked.

accept the conclusion that the condition is one of degeneration. No muscle or group should be condemned as useless till every effort, every position of advantage be tried out and exhausted (W. Colin McKenzie, "The Action of Muscles.")

Aside from disordered states of the nerves, altered states of the muscle are to be dealt with. In contracture there is hypertonia. In paresis there is hypotonia, sometimes flaccid paresis; in others hypertonia is confusingly blended with contracture or spasm or both.

In the case of purely psychopathic contractures suggestion or deep anesthesia may cause them to disappear. These may recur on regaining consciousness, sometimes half an hour before awaking. The so-called hysterical (psychogenetic or emotogenetic) element may not be eliminated by ordinary rational forms of treatment and only by protracted educative measures.

In serious wounds, civilian or military, any of these contractures or paralyses or admixtures of both, are likely to occur suddenly in men presumably sound and vigorous, hence probably no primary degeneration exists, or rarely.

The bulk of contractures are said to be found of reflex origin in war injuries. Hence we may proceed to attack an individual case with confidence of securing benefit. Often wounds involving the bones or the soft parts, and also cases without injury either to nerve trunks or big vessels extending to areas subjacent to the damaged point, demand particularized care. These, so Babinski says, produce reflex contractures under various aspects, intensities, and localities, both the paralytic and hypertonic forms. Occasionally, so he says, we meet complete flaccid paralysis, as of the hand and fingers consequent upon a wound of the second intercostal space, but such cases are so rare we have to deal for the most part with hypotonic states. Sensory disturbances, pain, and hyperesthesia often accompany.

Reflex disturbances may, of course, be the consequence of wounds of the nerves. Also Babinski mentions that the contractures may be complicated by fibrotendinous retraction and are to be differentiated only under anesthesia. It is interesting to note in this connection that some cases are aggravated by electricity and by massage (Sicard), yet are not emotional or hysterical (psychogenetic).

The measure upon which, in my opinion and experience up to date, we can best rely is the intelligent application of manipulation by the physician himself. After he has explored, experimented, learned the nature of the phenomena, even though the primary or dominant cause may still elude, only then can he safely entrust the case to an ordinary masseur with exact instructions which must not be exceeded.

Let me emphasize a fact gleaned from much experience, that the word "massage" is interpreted variously and often most confusingly. I have learned to disregard wholly the often dogmatic statements of most learned neurologists as to the indications pro and con. The only reliable decision as to "indications or contra-indications" can be reached by cautious personal handling of the part, beginning by explorations of the spinal subcenters through learning the status of the paravertebral structures, and by tracing down toward the periphery. Often there will be found evidence of hypertonus, sensory disturbances, hyperesthesia in associated muscle masses, in origin, *i.e.* points of exit or "nerve points," or in nerves in continuity, any or all of which may have been affected. These may have arisen reflexly, *i.e.* from the seat of peripheral irritation, or transferred to the cell bodies in the cord and thence afferently.

Experience and cautious exploration all the way from outlying points to the cord and back again, is alone capable of giving the information essential to apply treatment successfully.

That treatment should invariably or chiefly include persistent, consistent, and hopeful volitional training.

CASH PREMIUM ON HEALTH.

By FRANK WEHLE, M.D.,

BUFFALO, N. Y.

THE law most constant is the law of change. Some things change obviously, others hardly perceptibly; however, there is nothing which always remains the same, whether it is a solar system or an atom. To evolve, whether it is progression or retrogression purposeful or without purpose, is a law which is universal. In one of the buildings of the New York Society of Natural History is a classic representation of the evolution of the horse from a diminutive five-toed animal to that of its present status. Homo sapiens genus will soon be displayed in a similar manner. Compare the first steamboat, locomotive, automobile and aeroplane with the present day products; their metamorphoses were quite obvious. In the study of the history of medicine we learn that the barber was the precursor of the admirable and skilled surgeon of to-day. The barber sign symbolic of blood and bandage is still displayed. Recall the changes in physiology from the days of humours and dishumours to Harvey's discovery of the circulation of the blood; the changes in therapeusis from remedies like this—"take 12 young swallows out of the nest of rosemary; lavender and strawberry leaves of each a handful, bruise the swallows with their guts and feathers, then boil all in a sufficient quantity of fresh butter after you have strained it, then rub the part with it very well by the fire, etc," to the present day administration of specifics as diphtheria antitoxin and salvarsan. Consider the vast changes which have taken place in medical education as the elimination of some of the poorer medical schools, the increased premedical requirements, the innovation of the D.P.H. degree, and the rapid growth of the importance of preventive health methods.

In all evolution there are factors which divert, deter, and retard. At times these factors can be controlled and often a thing which is in itself vicious may be the cause of great good contrary to itself. Can the introduction of the compulsory insurance bills in our legislatures be of this nature? Will it give a stimulus to worthier and more constructive measures? Will it tend to break the profession's characteristic complaisance and cause it to take a more active and directing part in matters pertaining to the public health and to the profession's better economic condition; and, if there is to

be any reorganization, let those most directly concerned guide and control it, let it be from within the profession. So, like everything else, the relation of the physician to the public is rapidly changing, and if but an instant is given to realize this fact great advances ahead will be made. It would have been easier to appreciate this more fully had the Davenport bill been passed last March. Now is the psychological time for the medical fraternity to strike back for better health laws, better economic conditions and more protection against quacks and nostrums.

That there is need for the consideration of the subject of social insurance goes without saying, it already exists; trade unions, fraternal orders and industrial sick benefits are well known examples. This principle of protection has been used many years. The new propaganda has endeavored to extend it to greater numbers with the element of compulsion and other features which would make it a gigantic charitable institution with political and lay domination of the medical profession. One of the chief reasons for its adoption is the plea that there is a large amount of poverty due to sickness. The advocates of compulsory health insurance have lost sight entirely of the fact that sickness is largely caused by poverty and ignorance. Osler says the reasons for the lower death rate (which is the best criterion of public health) are firstly, the improved social condition of the people, better wages with better housing and better food; secondly, the education of the people, which has made great strides forward, a larger proportion are endeavoring to lead hygienic lives.

That there is no medical utopia at present and never will be most of us believe, or until we become supermen,—and to attain that standard will take so long that it is impractical to consider. That there is a serious sickness problem which is very truthfully and elaborately presented by the advocates of compulsory health insurance is admitted and cannot be ignored, but we also know that the doctors have been carrying more than their share of the expense of it. Realizing that there is this problem, it is also necessary to comprehend that compulsory health insurance will not solve it, but its solution is perhaps not entirely hopeless. That there will always be sickness and attendant pecuniary inconvenience is inevitable and it is very doubtful if compulsory health insurance would ameliorate these conditions so much as the present favorable conditions in which the wage earners find themselves to-day.

Any law which places a premium on an evil is a vicious one and an effective, expansive health law should be primarily and entirely a preventable measure. In order though that the State may intelligently try to draft such a law, it should first make a comprehensive survey which would include the total amount of sickness, attended and unattended, sufficient and inadequate medical care, days' loss and financial loss. And the first step to take to accomplish this would be to obtain from the State legislature sufficient funds for the State health department which, with the medical profession, should conduct the work.

A good feature of such a measure would place a premium on health, a real tangible premium, a cash premium. The principle involved would be that a citizen in good physical health is an asset to the community and in consequence should be compensated for this worth or his endeavor to secure a good physical condition. Thus, if the state taxed her citizens on the assumption that each one was physically unfit and remitted this tax upon his having received a physical examination, there would be in this way an entirely new attitude created towards the medical profession and a very attractive inducement for every citizen to be examined which is quite necessary in a radical innovation of this nature. As a preventive measure this would offer an effective means of doing what compulsory health insurance could not do, and it would not tend to lower the standard of the medical profession but would make it more important and elevate it to a higher level. It would place into the hands of every doctor the means of preventing disease, ameliorating existing conditions and warning of the approach of constitutional disorders. In this way the medical profession would actually be paid to maintain the health and prevent sickness, that this movement can be made quite popular is evidenced by the admiration that so many laymen speak of the Chinese doctor whom they believe practice on this basis.

That there is a crying need for universal physical examination has been shown conclusively during the draft period, and any medical officer who has had school inspection work can give a startling array of figures of defects as to what routine examination in children of school age present, and every doctor who has examined large numbers of apparently normal people is more often surprised than not as to the frequency of the occurrence of the abnormal. Consider the enormous amount of eye defects, impaired hearing, nasal obstructions, enlarged tonsils and adenoids, bad teeth, heart and lung conditions, blood conditions, mental diseases, scoliosis, hernia. varicose veins, hemorrhoids, phimosis, flat feet and club feet, which go unrecognized and untreated each year. There is no field of endeavor which is more undeveloped than that of medicine. There are more questions of laymen to be answered, more preventive advice to be given, more tonsils and adenoids to be removed, more scoliosis and flat feet to be corrected, and more other diseases and surgical conditions to be treated than all the doctors in New York State working twenty-four hours a day and seven days a week could ever hope to accomplish.

As in all innovations of this nature the first and most serious obstacle to its adoption would be the cry of an already overtaxed people of a burdensome cost. This could be met in some such way as this: Granting there are 10,000,000 people in New York State and each one was taxed $6.00 this would total $60,000,000. Assuming one-half to take advantage of the privilege there would thus be a refund of $30,000,000 for administration and for medical fees. Thus, he who would take advantage of it would gain in two ways: he would receive a valuable medical examination and recover his tax, and the one who had not taken advantage of it would deservingly pay for it. Universal physical examination should be in no way objectionable to the profession; it would enhance the profession by advancing pre-

ventive measures, and as every citizen would have unrestricted choice of physician it would obviate the disagreeable feature of the compulsory health insurance bill in which there was this restriction.

To recapitulate, I have endeavored to call attention to the following:

(1) The relative position of the physician to the public and his patient is rapidly changing.

(2) There is a tendency for outsiders to try to reorganize the medical profession by means of legislation which would be detrimental to the public and the profession.

(3) There is a serious health problem in a preventive and curative sense.

(4) The situation could be to a certain extent relieved by universal physical examination.

(5) A cash rebate would make this innovation popular and its cost would be paid for by the careless and objectors.

(6) And lastly, it would tend to make the medical profession more a profession of prevention than of cure.

To conclude, it has been endeavored to emphasize the fact that although the Davenport bill has not been passed laymen will again propose this, or one equally as vicious, which would be contrary to the best interests of both public and profession, that it would have to be opposed again, with cost in time and money, with conditions *quo ante*. Why not take antecedent methods in the quiescent period and propose something really beneficial to all concerned, which would bury the Davenport bill and its ilk in the grave of oblivion and clear the way for constructive measures. If compulsory health insurance could very nearly be made a reality why cannot universal physical examination actually be made so?

Before closing the writer wishes to say that he has a full and keen appreciation of the intensity and scope of this subject and that he is aware that it has taxed the minds and ability of some of the best sociological and medical men of the country, but if he has been able to open up any new avenue of thought on this subject his temerity will perhaps be forgiven.

585 Lafayette Avenue.

NOTES ON VENEREAL DISEASE CONTROL.

By HERMAN GOODMAN, B.S., M.D.,
NEW YORK.

INTEREST in the prevention of syphilis, gonorrhea, and chancroid, the so-called venereal diseases, made evident since the late war by the increase in the agencies for the abatement of the prostitute menace, and for the protection of men and women against these diseases, is deemed sufficient reason for the presentation of these observations.

The problem of venereal disease infection concerns the young men and women of the community, although no age is exempt from the possibility of infection. Among 383 Porto Rican men with gonorrhea or syphilis in whom I could definitely determine the age at which they were infected, 204, or over 52 per cent., had been infected between the ages of 20 and 24 inclusive. I give the table in full:

This study was made on men of the draft age, that is, between the ages of 21 and 31.[2]

AGE AT WHICH PATIENTS ACQUIRED VENEREAL DISEASE.

Age	Gonorrhea	Syphilis
11	0	1
12	0	1
14	0	1
15	2	4
16	1	4
17	7	8
18	7	10
19	14	8
20	19	19
21	28	24
22	26	25
23	21	18
24	24	10
25	17	14
26	4	8
27	8	5
28	8	5
29	7	6
30	12	6
31	0	1

For comparison, I give the following chart of age of infection with syphilis for 202 men, residents of New York City:

Age	Number	Age	Number
1	1	32	5
15	1	34	2
16	1	35	5
17	4	36	2
18	9	37	3
19	9	38	2
20	14	39	3
21	15	40	2
22	11	42	3
23	13	44	2
24	19	46	1
25	18	48	4
26	22	51	1
27	9	64	1
28	15	..	.
29	5	..	.
30	6	..	.
31	4	..	.

I have divided this group to demonstrate that of the 202 men, 166 had acquired their syphilitic infection before their thirty-second birthday; 45 per cent. of the 166 had been infected between the ages of 20 to 24 inclusive.

The infection at one year had been acquired by the patient from an infected wet-nurse. All except two of the other patients admitted infection by sexual contact. Less than one per cent. of men patients denied infection, or were ignorant of having been infected. As will be noted later, only one out of 1,320 women, of whom nearly 9 per cent. gave a strongly positive Wassermann reaction, knew that she had been infected.

At another of the islands of the Antilles group, I had the opportunuity of studying the reports of venereal disease for one year. The findings in full were:

Of the 37 early syphilitic cases 12 were reported between the ages of 20 and 24 in the men; 9 of the 18 early syphilitic cases were reported between the ages of 15 and 19 among the women; 35 chancroids of the 60 reported were in men between the ages of 20 and 24 inclusive; 28 cases of gonorrhea were reported in men between 20 and 24, all cases in men numbering 66; 7 of the 10 reported cases in females were less than 19 years old. One child of two was infected by a diseased sister; another girl of 11 was infected by her brother 13. One boy of 13 years was infected by his sister of 17.

It should be especially noted that although on this island the women slightly outnumber the men, the ratio of venereal disease *reported* is as 2 : 11.

This is of great significance, because these figures are based on the reports of physicians to the Health Office, and indicate that the woman is less frequently aware of the disease, and seldom, comparatively speaking, consults a doctor for venereal disease. The problem of the woman carrier of these diseases rests to a great extent on proper laboratory tests.

REPORT OF VENEREAL DISEASE AND AGE AT WHICH REPORTED.

Age	Syphilis						Chancroid		Gonorrhea

63						1				
66									1	
77									1	
			1						1	

I have summarized the findings thus:

REPORT OF VENEREAL DISEASE FOR ONE YEAR

Disease	Male	Female	Total
Syphilis—Primary	7	1	8
Secondary	30	18	48
Tertiary	17	10	27
Chancroid	60	1	61
Gonorrhea	66	10	76
	180	40	220

The following figures taken from my study, "The Wassermann Reaction and Miscarriages"[3], may prove of interest as indicating syphilitic infection among women seeking maternity care in a large institution in New York City.

Only *one* woman among the 1320 gave a history of having been known to be infected with syphilis, although approximately one woman out of each 11 gave a strongly positive Wassermann reaction, indicating in all probability a syphilitic infection. Infection with venereal diseases is almost universal among women practising sexual promiscuity. This holds true whether the prostitutes are of the so-called registered or clandestine group, as shown by this report of syphilis and gonorrhea:[4]

BLOOD WASSERMANN TEST ON 1,320 PREGNANT WOMEN[3]

Result	Number of Cases	Percentage
Negative	1,159	87.
Doubtful	12	0.9
1+	14	1.
2+	17	1.2
3+	29	2.
4+	89	6.7

Number examined	Type	Incidence rate
231	Registered, in district	91%
175	Registered, outside district	95%
302	Clandestine, unregistered	92%

In another city, of 456 prostitutes examined, 433 had either one or both diseases:

Number examined	Type	Incidence rate
299	Registered in district	95%
157	Registered outside district	96%

In an examination[5] of almost one thousand public prostitutes I found that 12 per cent. of the women had dangerously infectious syphilitic lesions, such as chancres, mucous patches, condylomata lata, and open skin syphilides. On routine blood examination 42 per cent. more were found to have four plus reactions, indicating in all probability a syphilitic infection. The incidence of gonorrhea among these women, as evidenced by clinical examination and by smears from the urethra, vagina, and cervix, was not less than 93 per cent. I give a chart summarizing by five-year periods the percentage with infectious syphilitic lesions, and the percentage with four plus positive Wassermann reactions, of 791 of these women:

Age Period	Percent with Infectious Lesions	Percent with Positive Wassermann
13–17	15	42
18–22	11	49
23–27	11	45
28–32	4	43
33–37	0	38
38–42	0	33
43–56	0	25

It is my purpose in this paper to outline the methods used in combating this scourge of the human race, and I do not think it amiss to enumerate a few headings:

Prevention.—1. Syphilis and gonorrhea are avoidable diseases. 2. Illicit intercourse is the chief cause of these diseases. 3. No prostitute can practise her profession without becoming infected. 4. There are no "private prostitutes." A man may think he is the only one receiving favors, but the other fellow is thinking the same. 5. Making it difficult for the prostitute to carry on her trade is one of the best ways to reduce the incidence of

venereal disease. 6. Continence, abstaining from sexual intercourse out of wedlock, is not dangerous to health. 7. If a man has the strength to keep away from prostitutes he will avoid syphilis and gonorrhea, and will not transmit these diseases to his innocent wife and children.

For Those Already Infected.—1. *Syphilis and gonorrhea are curable diseases.* It may take a long time. Start now. Visit a doctor or go to a hospital. Don't try self treatment. The druggist is not a doctor. Patent medicines do more harm than good. 2. Do not give your disease to others. Do not transmit it to innocent persons. Do not marry until you have the consent of your doctor. 3. If every case were properly treated, venereal diseases would soon cease to be.

Based on these headings, I prepared in one community, where I was advancing a sexual hygiene program, a statement somewhat like this:

An outline of activities planned to reduce the prevalence of the venereal diseases divides itself into three parts:

1. Social measures to diminish sexual temptations. These include the repression of prostitution, and the business of prostitution; also provision for proper social surroundings and legitimate recreation.

2. Education by means of lectures by medical and non-medical authorities. These lectures besides inculcating continence should explain the risk and waste of the venereal diseases. Pamphlets should be distributed which should be brief and which warn the reader of the venereal dangers. Exhibits and demonstrations, including moving pictures which have the approval of recognized authorities, should be given. An attempt should be made to reach the women and the influential women's organizations can do much by indorsing and supporting the program of social hygiene.

3. The medical program should include proper and easily accessible clinics for the treatment of all infected with venereal diseases. These clinics and hospitals should be under the jurisdiction of specialists in the care of skin and venereal diseases. Men and women should be treated, in some communities on separate days or at different hours. Facilities for free treatment for those unable to pay should be available. Hours at night for workers should be featured. Every effort should be made to keep the patients under treatment until non-infectious and cured. Emphasis should be placed upon the necessity of high standards of technique, and case records should be confidential. Provision should be made for laboratory demonstration of the germs which cause the venereal diseases for it is in the early stages when the clinical picture is not conclusive that the diseases are most amenable to treatment. Facilities for the serological tests are of great help, also.

Such a program has been successfully tried in other communities, and there is no reason why it cannot be introduced here, because its application is practical in all its essentials, and because the public is ready to support the complete program as rapidly as the details of its application to the community involved can be explained.

In the United States great strides have been made in the last five years. Congress has already appropriated millions of dollars to be divided among states which accept certain standards and provide certain facilities. In addition grants are given for research work to colleges and universities, and for scientific investigation. Institutions for the care and treatment of venereal disease carriers are being assisted. Any community seeking to provide for a sexual hygiene program should investigate the provisions of the congressional law appropriating these funds, as no doubt financial aid would be forthcoming. Unfortunately, only States and the District of Columbia may share in the $1,000,000 fund of payments to States for their health departments to use in protective medical measures relating to venereal diseases, and those isolated communities to which we owe some debt in this regard are not provided for. I speak for Alaska, Panama Zone, Guam, Virgin Islands, Porto Rico, Philippines, Haiti, and our military posts in China. My experience in four of these makes me feel that Congress has been a little forgetful of our young men in these localities where sexual temptation is at a great height.

That such a program of attack on the venereal diseases is a practical and not a visionary plan is proved by the remarkably low number of new infections among 12,000 men at one of our military camps, where I was in charge of the venereal disease control work. The annual rate for all new venereal disease was three per 1000 for the six months that the men were in camp. There were four new cases of syphilis, and 16 new cases of gonorrhea.

At another station, venereal disease infections dropped from 78 per 1000 to 6.09 per 1000 for periods of six months each, during the first when toleration of prostitutes was in vogue, and during the second when the men were limited to a community where prostitution is prohibited, and the stringent penalty of deportation awaits the guilty.

The doctor in practice has an important place in venereal disease control, for by his early recognition of the symptoms of these diseases and immediate appropriate treatment, the infectivity of the patient is reduced, and fresh infections prevented, Such prophylaxis by treatment should not be ignored.

RABELAIS' REMARKS ON THE THROAT.

BY DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO, CAL.

THE throat is not a well defined term; it may designate the front of the neck between the chin and the collar-bone, through which the windpipe and the gullet descend. It is also applied either to the fauces, or to the gullet, or to the larynx or to the windpipe. It may also include the whole neck. It is frequently used as a synonym for the voice, and was so employed in Rabelais' day. For instance, Anarchus, King of the Amaurots, was made prisoner by Panurge, and among other indignities, that worthy made his prisoner a street crier of green sauce. As an encouragement to cry louder, he exclaimed from time to time, "Tu as bonne gorge,"—You have a fine voice.[1]

In another situation, in describing the education of Gargantua by Ponocrates, it is said that they sang to the full extent of their throat, "a plaisir de gorge."[2]

As signifying the front of the neck, the word throat and what it stands for has always been of the highest interest to medical men. There is the beautiful chubby neck of the infant Gargantua with its eighteen double chins rippling down over the chest and abdomen;[3] there is the slender, stemlike neck of the adolescent female, with its beautiful fullness at the base, caused by the slightly enlarged thyroid gland. With advancing years the undue fat so easily acquired by the woman of lactating age, is followed by a reduction or a flabbiness of the subcutaneous adipose tissue. This is first noticed in the neck where the atonic skin falls into folds, dewlaps and wrinkles, and at the same time, the base of the neck flattens out, or becomes hollow, because of the diminishing thyroid gland. This, with the attendant seborrheic changes on the cutaneous surface, is undoubtedly what induced Browning to write:

"From the chin to the udder,
She was a thing to make you shudder."

As a contrast to this, there is the strong neck of the well built adult male, supported on each side by the outstanding pillars of the sternocleidomastoid muscles, the whole forming a fitting base and an easily flexible column on which to poise the fighting jaw and head.

Because of the neck being soft and slender and containing in an easily attainable, comparatively unprotected situation the great blood-vessels running to the head, the chief seat of consciousness, and also because there runs down the forward part of it the windpipe or trachea, also in this situation easily compressible, and leading when so compressed, to the interruption of the oxygen supply so necessary to the maintenance of consciousness and of life, the neck from the earliest times has been considered a favorite situation for causing death by compression. Rabelais, in his famous discussion of the uses to which the pantagruelion, or hemp plant, may be put, mentions in the first place the use of hemp as a rope for hanging.

Rabelais says that the pantagruelion or hemp plant compresses the passages through which pass out the merry sayings, and by which enter in the delicious morsels, and it does it more villainously than either angina or squinancy.[4] Squinancy is an old form of the word quinsy, and angina seems, indeed, to have included all strangling or obstructive diseases of the throat.

It appears that in Rabelais' day hanging was what a newspaper man would call "a live issue" or a "timely question."

Francis I of France, the original of the hero Pantagruel, had introduced an innovation in executions, which up to that time had been accomplished by withes and by strangulation. He changed to a hempen rope and suspension. In Scotland also they used to employ the willow withe, or woodie, as a means of ending an objectionable life, and this was the subject of many an old song as, for instance:

"And waefu' fa' the weary woodie," which in English would read, "And woefully falls the weary willow withe."

The employment of "the woodie" would appeal to the Scotch authorities as being cheap, and not appreciably increasing the civic tax burden.

It is true that Sir Walter Scott, who was no mean antiquarian, describes, in Quentin Durward, the deputies of Tristan l'Hermite, Trois Echelles and Petit André as going about plentifully supplied with rope. Tristan l'Hermite was the chief hangman of Louis XI, who reigned considerably before Francis I, and before Rabelais wrote his genial books. One must remember, however, that Sir Walter was that most improvident person among the Sons of Men, an improvident Scotchman, and that if there was an expensive way of doing a thing, he would choose it, and if there was an inexpensive, perfectly practicable way of doing a thing, Louis XI would choose it. It might probably be more historically correct to represent the two famous hangmen as supplied with bundles of switches, like old fashioned schoolmasters.

After Francis I, no notable improvement seems to have been made in the art of hanging, but there were attempts. Pepys, for instance, mentions that one of a great family was hanged with a silken halter of his own preparing, "not for honor only, but because it strangled more quickly."[5] They probably had not then introduced the scaffold and "drop," thereby entirely eliminating strangling. As a further refinement in capital punishment, it rested with America to introduce electrocution with its expensive apparatus. It is hoped that the economies incident to the war may cause a recurrence to simpler methods, especially in the case of traitors.

The throat is also regarded as a handy and effective place to grab an adversary when you wish to persuade him by violence, a la Tudesca, to your way of thinking, as for example, when in the battle of the sausages, the savage stout brain sausage, made a pass as if to seize Gymnast by the throat.[6]

The interest Rabelais had in the throat also may be seen in the names he gave to some of his principal characters. Grandgousier, or Big Throat, Gargantua and Gargamelle are all synonyms alluding to the appetite or swallowing capacity of the giants. These names originated in the region south of the Loire, as also did the popular traditions relating to them. In Languedoc, at the present time, Grandgousier is the name of the pelican, and it also signifies a gormandiser.[7]

Rabelais himself derives the name Gargantua from Grandgousier's joyous exclamation, "Que grand tu as le gosier!" ("What a big throat thou hast!") on hearing the first cry of his infant son.[8] This, of course, is facetious, but it indicates plainly the meaning Rabelais intended to give to the word.

Under the veil of a fight between the magpies and the jays, Rabelais wrote a whimsical account of the war between France and Brittany.[9] The jays, by their colors, azure and argent, represented France, and the magpies bore the Brittany ermine in their feathers.[10]. A jay belonging to Rabelais' uncle, who lived at Angers, broke his cage in order to foregather with his fellows. He attended the battle enthusiastically, and returned home wounded but satisfied. He was able to say two words, "Croquer pie," which besides its reference to magpies, was an invitation to drink. Because of this reiterated invitation to drink, he was called "Goitru," which

meant to fill the goitre, or throat, with drink." In modern life, the word goitre has acquired a different signification, although still clinging to the locality.

Medicolegal Notes.

Treatment of Gunshot Wounds—Expert Testimony.—In an action for damages for alleged improper surgical and medical treatment against a practising physician of San Francisco, it appeared that on April 24, 1916, the plaintiff received a gunshot wound in the right elbow, the bullet passing through the joint and shattering the bones. He was treated at the emergency hospital, where the wound was bandaged, and he returned to his home. During the evening of the same day the pain became very severe and he called the defendant, who administered a hypodermic. Next morning the defendant directed the plaintiff to go to a hospital for treatment, and while plaintiff was there he examined the wound, had *x*-ray pictures taken, and bandaged the arm again. The arm was badly swollen and inflamed, and it was decided that an operation was not advisable until this condition was relieved. On May 11 the swelling and inflammation having subsided, an operation was performed by the defendant, assisted by another surgeon, and the arm was placed in a plaster cast, through which an opening was made to allow access to the wound for cleansing and treatment. Later this cast was removed and the arm placed in splints. After the operation the plaintiff called regularly at the defendant's office and was treated by him. The arm showed signs of infection and discharged pus from the date of the operation till August 21. At this date, the wound having failed to heal, *x*-ray pictures were again taken, and the defendant advised the plaintiff that it would be necessary for him to undergo another operation. At this time the defendant stated to the plaintiff that he would take him to another physician, who had just returned from the war zone and who had had considerable experience with injuries of this character. Another physician, who was consulted, also advised another operation. The plaintiff thereupon discontinued his visits to the defendant's office and consulted physicians selected by him, who performed a second operation. After the second operation the wound healed rapidly, but the elbow remained stiffened.

It was held that what is or is not proper practice in examination and treatment by a physician and surgeon, or the usual practice and treatment, is a question for experts and can be established only by their testimony. The plaintiff contended that the defendant was negligent in not taking *x*-ray pictures after the operation and before August 21, as such pictures would have shown a condition calling for a second operation, which, it was argued, would have prevented the arm from becoming stiff. The only expert testimony offered by the plaintiff to establish the defendant's negligence was that of Dr. Coffey, who maintained that whether or not he, as a physician, would take *x*-ray pictures shortly after performing an operation such as was performed in the present case, would depend upon whether or not he was certain or uncertain of the integrity of his mechanical fixation in the operation.

Dr. Coffey also stated that the length of time that would be required to form a union of the bones, where the person was in good health, might be six months or a year or longer. It clearly appeared from his entire testimony that whether or not it would be desirable to take *x*-ray pictures at frequent intervals after an operation such as this would depend upon the individual case and the personal knowledge of the internal situation possessed by the man who had performed the operation; that, regardless of whether or not *x*-ray pictures had been taken at frequent intervals, it would have been unwise, according to the opinion of Dr. Coffey, to have operated during the time that the wound showed signs of infection; that in cases of this character it might be necessary to operate half a dozen times on a bone before getting a union. It was admitted that the wound was suppurating during the entire time it was being treated by the defendant, and that the treatment given it during this period was the treatment which Dr. Coffey testified he would himself have given in a similar case. Dr. Coffey testified that he had had twenty-seven years' experience as a physician and surgeon, and had handled over 18,000 fracture cases; that the injury to the plaintiff was a very serious injury; that it was such an injury as was likely to result in a stiff elbow; that it was an unusual injury; that not many doctors in that locality have had cases of precisely this kind; and that he himself had never had a case like it. It was held that the evidence was insufficient to establish negligence in treatment.

It was also held that the defendant's statement to the plaintiff that he would take him to Dr. Stoddard for the second operation because Dr. Stoddard had had more experience with such cases and had just returned from the war zone, and that he, the defendant, had not had a case like this one before, did not amount to an admission of incompetency and unskillfulness on the defendant's part. The fact that Dr. Stoddard was admitted to be more experienced and skillful along this particular line did not imply that the defendant did not possess that reasonable degree of learning and skill possessed by others of his profession in his locality. Though the determination of these questions necessitated the reversal of a judgment for the plaintiff, the court also remarked that there was no evidence that it would have been possible or likely by any course of treatment, no matter how skillful, to have restored to the plaintiff the full use of his arm after such an injury. The fact that a patient does not make a complete recovery raises no presumption of the absence of proper skill and attention upon the part of the attending physician.—Scherer v. Eidenmuller (Cal. App.), 187 Pac. 445.

Defective Information for Practising Without a License.—An information under the Illinois Medical Practice Act charged the defendant with practising medicine and surgery by treatment of a named person without a license to practice medicine and surgery in all their branches. The evidence showed that the defendant treated such person by a method of treatment without the use of drugs or medicine and without operative surgery; but as the information failed to charge a violation of that part of the statute forbidding such system or method of treatment without first obtaining a license so to do, it was held the conviction could not stand.—People v. Walker, Illinois Supreme Court, 126 N. E. 120.

Expert Evidence May Be Based on Testimony Heard and Documents Examined.—In a malpractice action it was held proper to ask a medical expert what was the proper medical treatment in a case such as that disclosed by the testimony he had heard, and the hospital records and *x*-ray photographs he had examined, instead of propounding to him a hypothetical question involving all the elements and matters to be taken into his consideration. It was also held that this examination of the witness did not invade the province of the jury, as calling for the expression of an expert opinion on the very matter to be submitted to them.—Wojciechowski v. Coryell (Mo.), 217 S. W. 638.

RADICULAR RADIOTHERAPY.

UNDER the above denomination, Zimmern and Cottenot refer to röntgenotherapy directed to the region of the emergence of the spinal nerves. It has for end the reduction or suppression of causes of irritation or compression of the nerve trunks, which appear to be the factors of painful syndromes usually designated under the term essential or primary neuralgia. In fact, the present-day tendency —founded upon the analysis of symptoms and associated phenomena—is to place the site of the morbid changes arising in rheumatismal or diathetic primary neuralgias also in those from cold, in the segment of origin of the nerve. Between the emergence from the cord and the formed nerve trunk, the root of a spinal nerve, after its passage through the meninges and vertebral foramen, is exposed to participation in the pathological processes which affect the organs with which it is related. A goodly number of cases of primary sciatica are unquestionably due to strangulation of the funiculus in the vertebral foramen, as has been pointed out by Sicard. In other instances the factor of irritation is probably seated more without, but is always juxtavertebral. The original seat of other neuralgias is certainly similar.

The clinical aspect offered by brachial neuralgia upholds this conception. This type is usually diffuse in its topographical distribution; the strict limitation to a single nerve territory is exceptional. Although the pain may occasionally seem to follow the course and distribution of one of the large trunks of the plexus, this localization is, in reality, never a pure one, because the other territories always participate in the neuralgia to a certain extent. Quite often the pain, which has no apparent systematization, shows by its distribution over several territories that the course of the irritation reaches the nerves of the plexus above the point where they have formed definitive trunks. Quite frequently, also, it will be found that percussion of the spinous apophysis of the last cervical vertebra will give rise to vertebral pain or to radiations down the limb which is the seat of the neuralgia.

Finally, this hypothesis relative to the topography of the causal lesion is confirmed by the results obtained by radicular radiotherapy. These results —very favorable in true sciatica—are still more striking in brachial neuralgia, perhaps for the very simple reason that the radicular region, which is much more superficial than in other segments of the spine, is more accessible to deep-seated irritation. In the large majority of cases it is probable that these neuralgias have an arthritis of the articulations of the cervical spine as a causal factor. Thus the irritation of the nerve is due to a periarthritis extending to the vertebral foramina. This is why rheumatism, gout, and "arthritism" are so often included among the etiological factors of neuralgia. The action of radicular radiography can, for this reason, be understood, either because it primarily acts upon the inflammatory lesions of the arthritis or periarthritis, or because it disengages the nerve from the infiltration compressing it. The first of these hypotheses is quite in accord with the results observed in the treatment of certain arthritides of the wrist, knee, etc. Independently of its action on the neuralgic syndrome, radicular radiotherapy has given some rather unexpected results in cases of neurodermatitis. Thus in a patient with pruritus of the upper limb, where local peripheral radiations remained ineffective, a single exposure over the point of emergence of the plexus resulted in a radical cure. Some cases of psoriasis seem to have benefited by this therapeutic measure. The latter facts would tend to prove that certain cases of neurodermatitis have a radicular origin, as do some dermatoses.

THE ETIOLOGY AND PATHOGENESIS OF ZONIFUGAL LICHEN PLANUS.

LICHEN PLANUS is an affection of adult life, being rare in infancy and advanced age, though some instances of linear lichen planus have been encountered in young children. The disease is more prone to occur in the nervous arthritic subject, usually following some extreme emotion or mental preoccupation, but this emotional origin may be absent. Briefly, the etiology of lichen planus is imperfectly understood, but one thing seems to be certain—it is not hereditary. Several pathogenic explanations have been put forward regarding the arrangement in lines of the zonifugal variety, the first being the vascular theory, which, however, cannot be sustained because the course of the lines follows that of neither the veins or arteries, nor of the lymphatics of the region in which the process arises.

There are three nervous theories which attempt to explain the lesion. Observers have quite naturally assumed that in its evolution a zonifugal lichen planus might follow the tract of a nerve, and in reality, in a very large number of cases, the linear bands correspond to a certain extent to this pathogenic supposition, but some instances have not seemed to fulfill the requirements. In one case recorded by Grelault the linear band appeared to follow exactly the course of the ulnar nerve in the forearm, but over the arm the eruptive elements were seen arranged in clusters that did not lie over the course of the nerve and could not correspond with its

branches, since the ulnar nerve does not give off any to the arm. In Djeladeddin-Moaktar's case the course followed by the cutaneous lesion was successively that of the great sciatic, the external popliteal, the anterior tibial, and its internal branch. Therefore, given these contradictory results, some other pathogenesis for the zonifugal type of the process had to be sought for, and then Philipson announced his theory based on the notion of Voigt's lines. Voigt's lines are those forming the boundaries of two adjacent nerve territories, while according to some observers they are likewise the seat of some types of eruption such as linear dermatoneuroses or linear nævi. Hallopeau has several times attempted to show that this theory is invalid in the large majority of cases, although he admits that some few cases are perfectly adaptable to it; but they are exceptional, as has been recently maintained by Laclyde in his thesis (Paris, 1913). Finally, there is the metameric theory, above all supported by Brissaud. According to this observer zonifugal lichen planus is dependent upon disturbances of the spinal metameres. By this theory should be explained those cases in which a lichen planus covers the area of several nerves each belonging to a different radicular level, and other unquestionable instances have been published by different writers which plead in favor of Brissaud's theory. For example, a case was seen at Professor Gaucher's clinic at the St. Louis Hospital, Paris, of metameric lichen planus of the lower limb, the eruption reproducing lesions of the first and second sacral pairs, according to Kocher's diagrams.

It would consequently seem that one should be eclectic in the pathogenesis of zonifugal lichen planus and conclude that although numerous cases of this cutaneous process are due to trophic disturbances, subjected to the sphere of influence of a peripheral nerve conductor, there are other undoubted instances, although rare, in which the localization seems to be under the control of a nerve root.

Histologically, there is an embryonal proliferation of the superficial stratum of the dermis, but this proliferation is more marked around the vessels, sudoriparous glands and hair follicles, to such a degree that the two latter structures undergo pressure atrophy. According to Balzer the lesion originates around the vessels. The umbilication is due to the sudoriparous ducts wrich prevent the skin from being raised up by connective tissue proliferation (Gaucher), while other writers look upon it as merely the trace of a hair follicle. As to the epidermis, it is thickened, this being the result of an internal proliferation of its cells.

MODERN THERAPEUTICS.

THE methods of practising medicine are undergoing a profound change, if not revolution. Lister, following the bacteriological principles discovered by Pasteur, recast surgery, and medicine seems as if it were to be regenerated by means of physics and biochemistry. A phase of preventive medicine which is frequently overlooked is that of the early diagnosis of disease and of the treatment thereof in such a way that it is prevented from going further. In the *Practitioner* for September, 1920, Sir Clifford Allbutt discusses the question of modern therapeutics and points out that in order to be successful in dealing with disease by the earliest diagnosis possible and by effectual treatment, besides the observation and recording of facts, we have to penetrate to inner affinities, even to molecular chemistry and physics; and moreover to bring to bear upon the events and their records the interpretation of reason and those methods of experiment which are the special contribution of our times.
